In exhausting diseases, cancer, anemia, etc., increase in the heart rate is believed to be due to an intoxication. Researches have demonstrated conclusively that the heart is invaded by specific organisms and toxins, such as occur in rheumatic fever, typhoid, diphtheria, etc.

In febrile diseases it is considered that an increase of 8 to 10 heart beats should equal a rise of temperature of one degree and in such diseases a rise of temperature increases the pulse rate and a fall diminishes it, excepting typhoid and meningitis.

It is believed that toxins, produced anywhere in the body, may evoke a rise of temperature and pulse, together with other symptoms. In all infections there is always some general intoxication produced (Pearce & Austin).

Without a nervous control the vascular system fails to meet important conditions of the normal circulation.

The vasomotor regulation system is therefore important. The vaso-constrictor fibres are present in numerous nerve trunks, but especially in those distributed to the skin. They arise from and are connected with the central nervous system, and have sympathetic connection. It is well known that, if the peripheral nerve end be stimulated, strong constriction of vessels occurs with blanching of the part and an increase of arterial pressure (Howell). The vasomotor nerves regulate the supply of blood, and their action constricting the arterioles probably produces the cold feeling (McKenzie) so common in leprosy.

6. These "toxic-febrile" attacks are usually followed by a severe lesions, most often with lo-

cal swelling, pus, pustules, bullae and later ulcers and severe glandular involvement.

7. Most of the patients have a low hemoglobin index—averaging from 35 to 55%—and a leucocytosis varying between 14 and 17 thousand. The urine in almost all cases shows an albuminuria, casts, abundance of cells and acid-fast bacilli.

8. Terminal or secondary infections are most often the cause of death.

I am under obligation to Dr. Lesley H. Spooner for his kindness in correcting and criticising the manuscript and for many valuable suggestions. I take this opportunity of thanking him.

Clinical Department.

A CASE OF AUTOTRANSPLANTATION OF BONE FOR NASAL DEFORMITY DUE TO SYPHILIS.*

BY LOUIS ARKIN, M.D., BOSTON,

Lecturer in Laryngology at Tufts College Medical School; Surgeon to Ear, Nose and Throat Department, Mt. Sinai Hospital; Assistant Surgeon to Ear Department, Boston Dispensary.

Rhinoplasty is the name given to the art of the surgery of the nose. Rhinoplastic operations are performed either to correct defects by replacing parts or the whole of the nose, or to reestablish functions lost by disease or trauma.

The substances used in rhinoplastic operations are inert materials or living tissue. The inert materials used may be metals, wood, rubber or paraffin. The living tissues used may be soft living tissue, such as skin, fat, muscle, periosteum; or hard living tissue such as cartilage or bone.

The methods used are first autotransplantation, that is, the use of tissue from one part to the other of the same individual; secondly, heterotransplantation, that is, the use of tissue from one individual to another; and thirdly, zoo-transplantation, that is, the use of tissues from lower animals in man.

This paper is a report of a rhinoplastic operation on a patient referred to me by my colleague, Dr. William B. Keeler. It was performed for the double purpose of restoring the function of nasal respiration, and for the correction of a nasal deformity for cosmetic reasons. The method used was that of autotransplantation of bone.

Family History. Nothing of importance with reference to this case. Married several years. No children.

Past History. Denies venereal. Several months before coming to see me she had some "discharge" from her nose for which she was treated for some

* Read before the Visiting Staff of the Mt. Sinai Hospital, February 11, 1915.

little time at the Massachusetts General Hospital, where she had her blood examined and a report of a positive Wassermann was given.

Present Illness. On her first visit to me on Feb. 22, 1913, I saw a woman of 29 years of age, married, of comparatively small stature, fairly well developed and nourished, but somewhat pale, and breathed through her mouth.

Physical Examination. Hair, color dark, somewhat coarse. No bald spots present. Temperature, 98.6. Pulse, 82. Respiration, 18. Pupils, reacted to light and distance and of equal size.

Tongue. Protruded straight and in the median line.

Teeth. Good condition.

Throat. Mucous membrane somewhat reddened, no patches, no abnormal discoloration; no membrane, no ulcerations nor scars present.

Skin. Dry, not sealy nor discolored.

Glands. Not generally enlarged.

Lungs. Both sides of chest moved equally, respiration and resonance good throughout.

Heart. Apex in the fifth left interspace inside the nipple line, not enlarged on percussion, no abnormal sounds or murmurs heard on auscultation.

Liver. Edge of liver not palpable below costal margin.

Spleen. Not felt.

Abdomen. Not distended, no abnormal masses felt, no pain nor tenderness.

Nervous System. Routine examination was without positive finding.

Report of a later examination of her urine while at the hospital was practically negative, except for an abnormal amount of leucocytes present and the slightest possible trace of albumin.

The general examination was, therefore, negative except for the following local condition of her nose:

Inspection of the front view of the outside of the nose showed that the part of the dorsum of the nose that extends from the anterior border of the nasal bones to the tip of the nose, presented a depression

Fig. 1.

or concavity (see Fig. 1 and Cast 1), causing the broadening of the nose at that place and a corresponding drooping of the facial expression in the same area, giving rise to a decided folding of the skin in the labio-facial angle.

Inspection of the side view of the outer surface of the nose showed a concavity of the anterior part, as in Fig. 2 and Cast 1.

CAST 1.

FIG. 2.

On palpation, the depression was found to begin just in front of the anterior border of the nasal bones and to extend down to, but not including, the tip. Touching the depressed area gave one a sense of non-support of the skin over this depression. Further palpation of the exterior showed that the tip of the nose was well supported by the columella and anterior part of the cartilaginous septum was intact; also that the cartilages of the alae were present, and that both inner and outer crura of the lower lateral cartilages were intact, and that the nasal bones were present and firm.

Examination of the nasal fossae or cavities showed that the nostrils were patent and of good size, but that that part of the septum just behind the nostrils, apparently corresponding to the depression on the outer surface, was bulging on either side, so much so, that it occluded both nasal cavities, causing her to breathe through the mouth. The mucous membrane of the nasal cavities was slightly reddened. On touching the swelling with the probe, it was found to be soft, not painful nor tender. The rest of the nasal cavities could not be made out on account of this bulging of the septum, which did not shrink with adrenalin. Posterior rhinoscopic examination only showed moderate hypertrophy of the posterior ends of the inferior turbinates.

Diagnosis. From this description, the most likely acute conditions present would be abscess of the septum, edema of the septum, hematoma and foreign body. It was not a local edema on account of the color of the swelling being red, rather than white or gray.

There was no history of accident nor any resistance on pressure to account for a foreign body or hematoma. There was no acute abscess, for she had no temperature; there was no pain or tenderness, and no pus nor blood obtained after introducing the needle of a glass hypodermic syringe.

As to the chronic conditions that might be present, tuberculosis was ruled out, for there was no tuberculous history, and no evidence of tuberculosis anywhere on the body. Tuberculosis of the nasal septum on the chances would give an ulcerated condition. If this were a neoplasm, the swelling would be hard if it were a fibroma. Sarcoma or carcinoma would result in a more or less rapid growth and an enlargement of the mass in all directions, and would, therefore, not give a depression of the nose. The symptom of cachexia was not evident. As to syphilis being the cause of this condition, it was quite likely, for syphilis is the frequent cause of such deformity, especially in the absence of accidents. So on Feb. 24, 1913, blood for a Wassermann test was obtained, and the report from Dr. Leary's Laboratory came back positive. She, therefore, had syphilis, and from her history of pus from her nose, several months previous, it seems that she had had a broken down gumma of the septum with pus formation at that time.

I explained to her the need of medicine before operation, and on March 3, and also on March 10, salvarsan was administered intravenously.

The next step was to correct the deformity. There are so many different varieties of deformities and no general rule of procedure for operation to go by, that each case is practically a law unto itself. In this case, we had two conditions present, the loss of nasal breathing, due to the occlusion of the nasal cavities by the swelling of the septum, and which, from our standpoint was the most important to correct; and the depression of the dorsum of the nose, which from the standpoint of the patient, was the real cause for seeking relief.

For such a moderate deformity, one would think of the use of the subcutaneous injection of paraffin to correct it. That method would, perhaps, not be out of place if that was all that we desired to do, but, the introduction of paraffin, besides the general objections to the use of it, would permanently increase the swelling of the septum and still further hinder the reestablishment of nasal breathing, so that paraffin here was positively contraindicated.

The fact that the tip of the nose was not affected and that the nasal bones were intact, it occurred that this case was a suitable one for the introduction of some solid support, one end to rest right at the tip of the nose in the median line between the two lower lateral cartilages, and the other end to rest against the anterior borders of the nasal bones, which place seemed to have some septal support. By this method it was thought that not only would the cosmetic factor be corrected, but that it would also lift up the septal mucous layers and thus re-establish the nasal breathing.

I decided that a piece of the anterior border of the tibia was suitable, for the reason that it was well suited as to shape and that it was easily accessible without damage to the patient.

On March 20, 1913, the patient was etherized, the nose and nostrils cleaned, the nostrils packed with sterile cotton, and an incision of about $\frac{1}{4}$ of an inch long made in the median line of the nose, just over the depression. The skin was separated from the underlying structures for a short distance laterally, and especial care taken to bare the anterior borders of the nasal bones from periosteum, and also to make a good depression for the reception of the anterior end of the transplanted bone. After this pocket was made, a piece of gauze was covered over the nose, and a piece of the anterior border of the right tibia $\frac{5}{8}$ inch long by $\frac{3}{8}$ inch wide, with its periosteum, was obtained and inserted into the pocket prepared in the nose after shaping the piece of bone for its new position. The transplanted bone seemed to give the nose a perfect contour, so the nasal wound was sewed up subcutaneously with horse hair. A small dressing kept in place with strips of adhesive plaster was put on. The leg wound was sewed up with five interrupted sutures and dressed. The patient made a good ether recovery. The patient left the hospital on March 28, nine days after admission. She made an uneventful recovery. Both wounds healed by first intention. While in the hospital, she received daily inunctions of unguentum hydrargrum. On the fourth day the nasal suture was removed and the parts kept in place by adhesive plaster strips. On March 30, two days after leaving the hospital, and ten days after the operation, the leg sutures were removed. On March 27, while in the hospital I referred the patient for a third injection of salvarsan.

On Apr. 3, she went home, down Maine, perfectly satisfied with the cosmetic results, and she breathed through her nose.

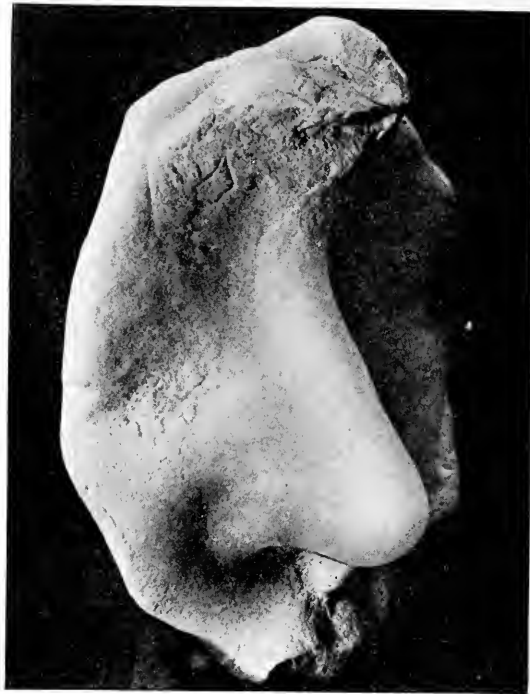

She reported again May 23, about nine weeks after the operation. The condition was perfect. The patient was delighted with the looks of her nose, and nasal breathing was excellent. The swelling of the septum was not apparent. The picture (Fig. 3) was sent to me and Cast No. 2 was taken the next day.

FIG. 3.

The operation reestablished nasal breathing by lifting up the ballooned-out septal mucous membrane and also corrected the nasal deformity.

I did not make my nasal incision intranasally for fear of infection from the nose itself, which would be likely to occur more especially on account of the lowering of resistance by the syphilitic process. I might have made my incision on the columella of the

CAST 2.

nose where it would not be likely to be seen, but the present wound, about nine weeks after the operation was not conspicuous and could not be seen except on close observation.

She was transferred to her local doctor in her own state with instructions to keep up the anti-syphilitic treatment, and his last report, Jan. 18, 1915, about twenty-two months after the operation, was that he had given her two doses of neosalvarsan since the operation, but that the end result of the operation was "extra fine," as he expressed it.

I report this case for the following two reasons: First, the importance of selecting the proper surgical procedure in each case; and secondly, the difficulty of making a diagnosis even after a thorough physical examination.

MYXEDEMA SIMULATING NEPHRITIS.

BY WM. DUNCAN REID, M.D., NEWTON, MASS.

THE surprising fact that this case was incorrectly diagnosed over a period of years, first by a homeopathic teacher of medicine and later by three general practitioners, one of whom was a homeopath, and by a nose and throat specialist, all of Boston or Greater Boston, is to us good evidence that a report of this case may be of suggestive value to some other practitioners. The writer frankly confesses that he only made the correct diagnosis as a result of reading the special lecture on "Thyroid Deficiency" delivered by Prof. Eugene Hertoghe, of Antwerp,

Belgium, at the New York Polyclinic Medical School and Hospital, April 14, 1914. This was published in the *Medical Record*, Sept. 19, 1914. Hertoghe's graphic description of his first case, of falling into the error of diagnosing it as chronic nephritis, as the physicians preceding him had done, and of finally diagnosing myxedema and curing the patient, almost describes our patient. The unusual number of impressive photographs of patients at different stages of the disease and Hertoghe's admirable exposition of thyroid deficiency, put his paper in a class such that to our mind all should read it. An abbreviated history of our case is as follows:—

MRS. G. O. 69 years, Aug. 6, 1913. Called to see patient for treatment of pain in lower back. Knew that patient was on nephritic diet and had had chronic nephritis for years, and saw no reason to doubt this. Urine, 2 quarts, clear, slightly acid, 1914. albumen, slight possible trace; sugar, 0.

Sediment, no casts or blood.

Sept. 6, 1913. Patient as before save for increased weakness. Pulse soft, heart sounds faint, some râles at base of lungs. Prescribed moderate stimulation and improvement was reported by phone. Both times gave unfavorable prognosis. On reading Hertoghe's paper we at once realized the correct diagnosis and asked permission to see the patient who, although practically bedridden, had not required a physician's services for over a year.

Nov. 7, 1914. History (from sister by persistent questioning).

Family History. Sister had thyroid trouble with generalized swelling at 65, and now takes thyroid medication regularly. Mother died at 79, preceded by 5 years of inanition. No children, no miscarriages.

Previous History. Good health first 4 decades of life. Denies rheumatism. Catamenia not thought to have been abnormal. Menopause at 45. About 20 years ago gradual appearance of "terrible sick turns" with nausea. Present condition believed to have begun gradually 10 years ago, when physician, a medical specialist, said she had chronic nephritis and should go to a sanitarium for treatment by diet, etc. Did not accept this advice, but remained under this physician's care for one year. In the past six to eight years each physician who has seen patient has warned family of impending uremia. Specimen examined June, 1914, at the Boston City Hospital Laboratory is said to have had very little albumen and no renal elements microscopically. Disagreeable hemorrhage a few years ago following extraction of a tooth. Up until 15 years ago patient was proud of a fine head of hair.

Present Illness. A continuation of the above with practical confinement to bed past five years. Weak, heavy, swollen, deaf, eyesight poor, always cold, never perspires, eats fairly well, dull. Never has headache. Much lumbar pain of moderate intensity. Complaints of difficulty in swallowing, and of being "so stupid."

Physical Examination. Lying propped up on pillows. Much bloated. Hears with difficulty, replies sluggishly and dropped asleep several times during examination. Voice has a surprisingly thick, coarse and husky tone. Marked alopecia extending to parietal and occipital regions, partly concealed by manner of arranging hair. Eyebrows thin. Cir-

Mrs. G. O., Nov. 14, 1914.

cular area about 2 inches in diameter of pinkish flush over each cheek bone. Extreme puffing above and below eyes, which with marked chemosis of left conjunctiva almost closes that eye. Lips very thick, tongue swollen, teeth absent save for few necrotic snags, gums thickened, and all buccal mucous membranes present thickened and grayish appearance.

Neck, very thick, no palpable glands. Chest covered with thick pads of tissue, obscuring landmarks. Lungs appear normal save for few râles at bases. Heart, area not enlarged, apex in nipple line. Impulse not felt. Sounds faint, no murmurs. Pulses, equal, very soft, regular, rate 80. Lower back and legs pit slightly on prolonged pressure. Reflexes normal. Skin very dry, thick and scaling in many places. Nails rough and lined.

Blood pressure, systolic 140, diastolic 85.

Urine, normal, cloudy, acid, 1017, no albumen, no sugar. Sediment, squamous cells and detritus. Few small hyalin and granular casts seen. Repeated examinations later failed to show but a small trace of albumen with moderate number of hyalin and granular casts. No fat or blood seen at any time. No acetone or diacetic acid.

Hemoglobin 60%.

Treatment. Compressed tablets of thyroid gland desiccated (Parke, Davis and Company), gr. 1 t.i.d., controlling dose by daily weighing of patient.

Subsequent History. Within one week the change was theatrical. Great diminution of edema with entire change of appearance of face. Patient became lively and happy, speaking intelligently and in a rather musical and soft voice. Hearing greatly improved. At end of second week patient heard church bells ringing, the first time for 5 years. Skin desquamated freely and gradually took on a nearly normal appearance. All this was accompanied by some nervousness, itching, pain in the limbs, elevation of pulse rate to 105, and at first profuse diuresis. Weight (not obtainable at first) was 139.5 lbs. on Nov. 19, although it was obvious that a marked drop in weight had occurred since the starting of the thyroid therapy. Weight rose slowly to 144 lbs. about Nov. 28, perhaps due to our letting up a little on the amount of thyroid administered.

About Dec. 1, 1914 broncho-pneumonia set in. All other improvements in patient had increased in amount.

Dec. 5, seen in consultation by Dr. Edward N. Libby, of Boston, who absolutely confirmed the diagnosis of myxedema with broncho-pneumonia as a complication.

Ophthalmoscopic examination (by Dr. Libby) showed normal fundi save for slight blurring of the edges of the optic disks.

Dec. 7, 1914. Death from broncho-pneumonia.

Remarks. This case in its final state resembled chronic nephritis mostly by the general aspect of marked edema and the small trace of albumen often present. Among the strong points aiding in the correct diagnosis were, the absence of hypertrophy of the heart, increased blood pressure, casts with fat, blood or cells on them, or nephritic changes in the fundi. The trophic changes in hair, teeth, skin and nails, generalized edema, with but slight pitting, erythematous patches on the cheeks, hebetude, deafness, changed voice, chilliness, absence of perspiration,—all are consistent with diagnosis of myxedema.

The history of severe hemorrhage after extraction of a tooth is suggestive of thyroid deficiency.

The long duration of a condition in which several different physicians warned of impending uremic convulsions without even the occurrence of a headache in the patient, pointed to a possible error in diagnosis.

The family history is of significance, and we find by reading various papers by Hertoghe and others that the digestive attacks may have been connected with disturbance of the thyroid gland.

The result of the thyroid therapy was conclusive. We believe the broncho-pneumonia to have been merely an unfortunate coincidence.

Personally knowing the high calibre of the men who erred in diagnosing this case we believe that there are other cases of this type which can be recognized if those in charge will again consider their patients, with myxedema as a possible diagnosis.

Reports of Societies

FALL MEETING OF THE NEW ENGLAND BRANCH OF THE AMERICAN UROLOGICAL ASSOCIATION.

HELD AT THE HARVARD CLUB, BOSTON, NOV. 30, 1914.

President, A. L. CHUTE, M.D., Boston.
Secretary, R. F. O'NEIL, M.D., Boston.

Presentation of patients, specimens, instruments, and the reports of cases.

RUSTLESS SOUNDS.

DR. O. R. T. L'ESPERANCE, Boston: About two years ago I tried to get some rustless sounds, and wrote to different manufacturers in the United States. Mr. Bard took upon himself the trouble of writing abroad to some of the foreign houses, but we did not get any encouragement. They did not seem to know of any metal that could be used.

Finally, here in Boston, I happened to find a die-maker who said that he thought he had the metal that would do, and he submitted a sample of a sound. I tested it by leaving it in the sterilizer

twelve days, boiling anywhere from six to nine hours a day, and it showed no signs of rust or wear and tear. I immediately gave him an order to make up a set of sounds.

They differ slightly in shape from the ordinary sound. The dilatation is between two points only, and the end is a little more tapered than the average sound, allowing more gradual dilatation. The old sounds are very blunt, and sometimes you have trouble in getting them started. As the meatus is the smallest part of the canal, the patient often complains of stretching at that point. The shaft of this sound is well graduated toward the handle so that there is no discomfort from prolonged dilatation. The feeling of the metal is very smooth and velvety. It does not lose this quality, and as it is not plated, rough places will not form.

In regard to the cost of this sound, the man said they could be made up for a dollar apiece, so that when you were paying eighty cents for the old sounds originally, and then paying extra to have them re-plated, it would really be economy in the end to have these.

The metal is nickel steel. Its melting point is about 1360° C., which ought to stand the average boiling.

SPECIMEN OF PYONEPHROSIS IN INFANTILE(?) KIDNEY.

DR. HORACE BINNEY, Boston: This patient was a young man about thirty years of age, whose past history was that ten years ago he came to the hospital with some urinary symptoms, frequency and slight pain, which promptly yielded to treatment in the out-patient department. His history subsequent to that time was negative.

Three months ago he began to feel mean, as he expressed it, lost weight and had a recurrence of his former symptoms, frequency and pain. He was examined in the out-patient department, and cystoscopy by the man on duty there, performed, who found an inflamed condition about the right ureteral orifice. Catheterization showed pus coming from the right kidney. Urine from the left kidney was normal, and the combined renal function was normal by the "red" test. From the fact that he had lost weight and had had night sweats, besides the urinary symptoms, we thought it was probably tuberculosis. The man was pretty uncomfortable, and we decided to operate. I started to take out what I supposed would be his tubercular right kidney. In getting down to the kidney region, I found a good many adhesions to the peri-renal fat, and blunt dissection failed to reveal any kidney. I got up to the liver before I discovered that there was not any kidney there. I then went lower, dissected out the ureter and followed that up into an indefinite, soft mass of what seemed at first to be fat, and shortly I made out a perfectly soft flabby renal pelvis, with no kidney, which it was not difficult to remove.

The specimen has been split on the median side, so that you are looking towards what there was of a renal cortex. There appears to be a slight degree of pyonephrosis.

Dr. Mallory examined a small bit of the cortex and found a few tubules. His first impression was that it was the result of early pyonephrosis of a normal kidney. I asked him if it could not be an infantile kidney, and he is not prepared to say it is not.

These things are apparently pretty rare. I have not looked over the literature at all thoroughly, but I

FIG. 3.—Congenital Aplasia of the Kidney. Renal pelvis laid open exposing pelvic aspect of dilated calyces. Probe in ureter.

did find an article by Braasch, who had seen seven, only one of which was diagnosed clinically. He says it is almost impossible to diagnose them, but he does not state how the diagnosis was made. Of course, catheterization of the ureters may give light.

But, practically, a catheter cannot always be kept in long enough to make sure that we get a sufficient quantity. I do not know how one can be sure of making the diagnosis, particularly when the urine contains pus, suggesting that the low function is the result of renal destruction.

DISCUSSION.

DR. H. CABOT, Boston: Apropos of the sounds presented by Dr. L'Esperance, it seems to me that they would be particularly valuable for hospital work. We all know that in hospital work sounds get into shocking condition, and often do more harm than good. At the hospital we have three sets, and with at least one of them constantly being fixed, you never have a decent sound in the place. If there is such a thing as a rustless sound, I have no doubt the hospitals would be glad to know about it.

I am interested in Dr. Binney's case. Dr. Geraghty raised that question, and pointed out that the diagnosis could be made on an infantile kidney by systematic tests of function and disproportion between the kidneys. We have had one case of a patient in the medical wards, and there was disproportion between the kidneys.—a small though normal kidney on one side, and a large normal kidney on the other. There was some chronic nephritis on both sides. The patient died of chronic arteriosclerosis. Almost all the work was being done by one kidney, though the time of function was equal and symmetrical. These kidneys are normal except that they are small. They will do everything except a normal amount of work. They will start function on time.

SPECIMENS OF CALCIC OVALATE CALCULI.

DR. GEORGE A. MATTESON, Providence: I have to show 10 "jackstone" calculi removed from the bladder in a case of prostatic hypertrophy. They were lying free in the bladder and were easily removed at the preliminary cystostomy. Stones of this form are said to consist of pure oxalate of lime. They are well pictured in the frontispiece of Kelly and Burnam's book. Every gradation of their development is shown in my specimen, from the smooth sphere to the many-branched coral-like forms.

DISCUSSION.

DR. J. B. BLAKE, Boston: This sound reminds me of a set which were in use in Vienna twenty-five years ago when I was there. They had in common this taper in the bend, but differing from these the Vienna sounds were at least two inches longer, and correspondingly heavy. They were so long that with a little care they would almost fall into the bladder without having to be pushed in, which is a considerable advantage.

I should prefer them if the curve was a little less sharp and a little more flattened at the point. I should think it would hardly be necessary to make them quite so tapering toward the handle.

In regard to the stones which Dr. Matteson showed, I had a similar case of five stones, thicker and a little larger than these, but the same unusual shape.

SPECIMEN OF URETERAL CALCULUS.

DR. R. F. O'NEIL, Boston: This calculus was passed by a patient whom I saw a short time ago. You see it is over $\frac{1}{2}$ inch long, $\frac{1}{4}$ inch thick, and very rough. Some months previously he had had symptoms referable to the right upper quadrant of the abdomen and was thought to have gall-stones. X-ray at that time failed to show the calculus. There was nothing in particular to point to the kidney. Later he had a typical attack of renal colic with hematuria and I was asked to cystoscope him. On doing so, I found this calculus protruding part way from the very edematous right ureter. I tried to dislodge it with a ureter catheter, but succeeded only in pushing it back. I then injected oil into the ureter, thinking he would probably pass the stone, which he did, but he had considerable difficulty in passing it through the urethra.

BILATERAL URETEROSTOMY FOR PALLIATION IN A CASE OF TUMOR OF THE BLADDER.

DR. R. F. O'NEIL: These are photographs of a patient upon whom I performed a bilateral ureterostomy about 5 weeks ago. He is a man of 60 with the following history: He first came to the Hospital about $21\frac{1}{2}$ years ago with an acute retention due to clots. The bladder was half way to the umbilicus, and clots and fresh blood oozed from the meatus. A cystoscopy was done, but beyond the fact that there was a growth near the base, nothing more could be made out because of bleeding. He was sent into the House and Dr. George G. Smith did an immediate suprapubic cystotomy under spinal anesthesia (the patient's condition was poor, he having a bronchitis and rapid pulse), and removed a papilloma about the size of a small walnut near the right ureteric orifice. It had a small pedicle and part of the bladder wall was resected as well. The patient made a good operative recovery and left the Hospital in two weeks.

He failed to return for observation as directed and was not seen again for about six months, when he came in because of a return of the hematuria. Cystoscopy at that time showed a recurrence at site of original growth and other smaller tumors at different points. He was treated by high frequency applications, at first with apparent success, but he was irregular in his attendance and cystoscopy became more difficult. The character of the large growth had changed to a broad based tumor, involving the right ureter, and he was having pain and tenderness in the right kidney region. His urinary symptoms were distressing. It was evident that no partial resection of the bladder was possible, so he was sent in for this preliminary side-tracking operation, to be followed by total cystectomy with hopes of obtaining a radical cure. At the time of the ureterostomy, however, I was able to palpate the pelvis and found a chain of glands along the sacrum and extending up the right side of the spine, which has precluded any attempt at complete cure by further operation.

The usual oblique skin incision was made just inside the crest of the ilium, and by means of a muscle splitting operation, the ureters were picked up extra-peritoneally at the brim of the pelvis, freed down towards the bladder, cut and then freed to the kidney. The ends were brought out by means of a clamp through a stab wound in the back, at a spot on the skin which had been previously marked as the best place to apply some form of apparatus. Care was taken that the curve of the ureter should be gradual and free from kinks, the ends of the ureters were not sutured to the skin, but left protruding about an inch and a half. (See cuts Nos. 1

which connect with a receptacle in front. (See cut 4.) There is no irritation of the skin and so far no renal infection.*

FIG. 3.—Bilateral Ureterostomy.

Six weeks after operation. Ureters have been trimmed off close to the skin.

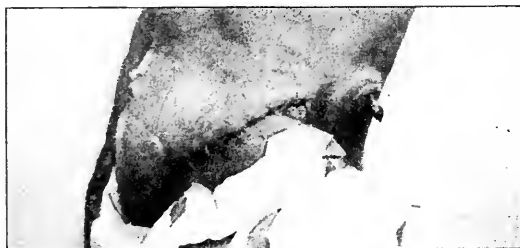

FIG. 1.—Bilateral Ureterostomy.

Two weeks after operation. Lateral views. Note protrusion of ureter.

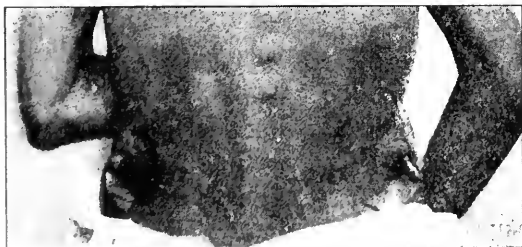

FIG. 2.—Bilateral Ureterostomy.

Two weeks after operation. Back view. Note protrusion of ureters.

and 2.) The right ureter was distinctly thickened and peristalsis was active. The ureters function normally and a jet is thrown several inches. He has been kept perfectly dry by means of an improvised apparatus made of soft rubber ring pessaries and glass tubes kept on with plaster straps and leading to a small bottle on each side. A permanent apparatus is being made, consisting of two cups

FIG. 4.—Bilateral Ureterostomy.

Permanent drainage apparatus.

* Since reporting this case, it is of interest to add that infection of the cut end of the right ureter took place following the slight operation of shortening the stump and the patient developed a typical attack of pyelitis with temperature, due to colon bacillus.

The ureters became somewhat edematous, but sloughed only a little. As they have probably retracted all they are going to, they were cut off close to the skin this morning, as they were too long to admit of an apparatus being applied. (See cut 3.)

As has been said, the complete procedure cannot be carried out in this case. But as a palliative procedure, I consider it a success. The man is entirely relieved of his symptoms, is kept dry and will shortly go home when his apparatus is ready.*

DISCUSSION.

DR. H. CABOT, Boston: I think the point of this operation, at least the point so far as I am concerned, is that the operation done in this way enables you to make your patients comfortable. In the past I have not believed that the patients were essentially more comfortable than they would be with a cystostomy. The point of difference is that in the first place we bring the ureters out in the back at a point where an ordinary glass tumbler will fit between the crest of the ilium and the ribs. Mark the outline of it. Bring your ureter out in the center of that circle, pull it out and leave it dangling in the air so that it can adjust itself where it wants to. Do not cut it off at all. The result is that you have a projection here to fit your apparatus over. The difficulty with the previous methods I have used is that, instead of having a projection over which to fit apparatus, you have a hole. It is the simplest thing in the world to fit an apparatus over a ureter brought out in this way. We have now another patient operated on some six months ago, a woman with cancer of bladder secondary to cancer of uterus. She has no trouble, has gained weight and keeps perfectly dry.

This will go a long way to make me use this method as against nephrostomy, which I have found more difficult and carrying a greater mortality.

DR. GUY L. HUNNER of Baltimore read a paper entitled,

RARE TYPE OF BLADDER ULCER IN WOMEN. REPORT OF CASES.¹

DR. A. H. CROSBIE of Boston read a paper entitled,

EPIDIDYMYOTOMY FOR ACUTE EPIDIDYMITIS AS AN OUT-PATIENT PROCEDURE.²

DISCUSSION OF DR. HUNNER'S PAPER.

DR. A. L. CHUTE, Boston: Dr. Hunner's cases of ulcer of the bladder seem to be confined to women. Perhaps that is because Dr. Hunner confines his practice entirely to women. I have seen recently a man who has three ulcerated spots on the posterior bladder wall, that are like the conditions Dr. Hun-

* Feb. 17, 1915. The patient left the hospital shortly after the above report and returned to the out-patient for observation. He said he was greatly tortured by passing thick material from his bladder and brought in a bottle containing several ounces of thick body foul fluid. This condition, a secretion from the growth, came worse and he was readmitted, some days passing 6 or 8 ounces of fluid. Because of this I did a suprapubic cystostomy under spinal anesthesia and with the curette and cautery removed much as I could of several large growths. This operation gave relief, the suprapubic fistula remains but gives no trouble. Following this he complained of pain becoming more severe in the right sacral regions. We thought this was probably due to extension of the growth; finally a tender spot developed about the middle of the right border of the sacrum. There was no temperature and it was thought he might have an abscess, the area was aspirated but nothing obtained. An abscess, however, did later develop at that point, and was opened. I think it undoubtedly came from infection and extension of the growth outside the bladder. The ureterostomies are still working well.

ner describes, but more intense. I have been unable to find an etiology for this condition and have been treating him for a short time with applications of the high frequency current, without, as yet, any particular change.

DR. H. CABOT, Boston: I find myself handicapped by the fact that I do not feel as if I knew anything about it.

It is fair to say that I have seen a group of cases which may well prove to belong to this class, in which the symptoms are very much those which Dr. Hunner describes, and I have not found lesions which seem to account for these. I have not been sharp-sighted enough. I have been looking for more gross lesions, and I have not seen them. I shall be interested to look for this lesion because there is a group of irritable bladders which most of us have regarded as not clearly organic.

The very slight changes in the urine I have been inclined to attribute to the urethra. As far as I am concerned, this opens up a very interesting field for looking over cases which I have previously overlooked.

DR. H. C. PITTS: I should like to speak about a patient of mine who has given me a varied experience for a number of years.

She was referred to me some eight years ago with a history of very persistent bladder symptoms, extending over a period of fifteen years. At one time she had had an opening made in the bladder, and left open for four months without benefit.

I cystoscoped her and found one of those angular ulcers at the right vertex. I treated her for several years with silver nitrate and bichloride instillations, and with over-distention, but made no direct applications at that time. She finally consented to operation.

With the bladder open, I found it extremely difficult to locate the ulcer. I excised what I supposed was the ulcer, but probably did not excise enough of the bladder wall, because she had a return of symptoms soon after leaving the hospital, and the cystoscope showed a return of the ulceration in about the same location.

I treated her after that, at first with direct applications of strong silver nitrate solution and later with fused silver nitrate on a silver probe. At the present time the ulcer is healed, and her old symptoms are gone. She does have some frequency, which I think is due to a contracted bladder. When I treated her before with over-distention, the only result I got was hemorrhage and an increase in symptoms, but lately when I have distended the bladder, there has been no hemorrhage, but a decided lessening of the frequency. Frequency is the only thing she complains of at the present time.

DR. J. H. CUNNINGHAM, JR., Boston: I have listened to this paper with much interest and feel that we may owe much to Dr. Hunner, for presenting to us a subject which, so far as I know, is an entirely new interpretation of a lesion which we occasionally observe in the bladder.

I have been very much disturbed by having patients come with the symptoms which Dr. Hunner describes, and I feel sure that I have observed, at times, the sort of lesions that he pictures, but I have never attached the importance to them that Dr. Hunner does, and yet I have seldom found other lesions to account for the symptoms.

The psychology of the nervous woman is something that has always disturbed me much, and I

¹ See page 660.

² See page 664.

have been inclined to pass these small lesions by when I have found them and attributed the symptoms to some other disturbance not determined. There is no question that these women are suffering (the cases I have seen have been women), and I have seldom been able to do anything for them.

On a few occasions, I have found the condition described associated with a caruncle. By removing the caruncle these patients received much benefit, yet the symptoms sometimes recurred, and it may be that the rather extensive operation which Dr. Hunner advises is the correct procedure. I shall be much interested to learn Dr. Hunner's view after longer experience with this condition and the operation that he advises.

I would like to know what the histology and the bacteriology of these ulcers may be, if it has been worked up.

DR. FRANK A. PEMBERTON, Boston: I have one patient similar to those Dr. Hunner describes. I have taken cultures of her urine three times and found no growth. I cauterized the area a year ago with silver nitrate; she was much better for a month, and then her symptoms returned. She has had all kinds of local treatment and is no better.

DR. G. O. CLARK, Boston: I have nothing to add, but I should like to ask Dr. Hunner whether these lesions are seen as easily with the Nitze cystoscope as with Dr. Kelly's method.

I am also very much interested in the histology of the ulcer, and should like very much to see it microscopically.

DR. G. G. SMITH, Boston: I have seen two or three women with symptoms such as Dr. Hunner has described, one of whom I was unable to help, and another whom I did help a great deal by dilatation of the urethra. She seemed to be very similar to some of the cases of Dr. Hunner. She had a little pus and blood in the urine and at first a few cocci and bacilli in the urine. These disappeared, and her symptoms were entirely relieved.

Closed by DR. HUNNER: Dr. Chute spoke of the high frequency treatment. Thus far I have treated only two cases in this manner, and each case had excessive pain afterwards and refused to have another treatment. As I stated, my last case is still being treated by applications of ten per cent. silver nitrate and is being kept fairly comfortable. I have intended trying the applications of the silver nitrate stick, or direct cauterization with the electric wire. It would seem that if anything will take the place of excision for these cases it will be some such radical measure that will get deep enough to clean up the floor of the ulcer.

Dr. Cabot thinks that he may have seen one or two of these cases and overlooked them because of the slight mucosa changes. This is one characteristic of these cases. The white scar tissue is as likely to attract your attention as is the slight congestion area. If you are in doubt touch them with an instrument over the congested area and see if they do not ooze.

I have been pleased in reading Dr. Tenney's paper on "Cystitis—An Incomplete Diagnosis," and believe that we are dealing with a class of cases which will take another fairly large group out of that limbo of our ignorance, the so-called "irritable bladder."

Dr. Cabot says that he found slight changes in the urine, which he attributed to urethritis. In men you have to differentiate with your multiple glass

test. In women the presence of any leucocytes or red blood cells in a catheterized specimen of urine indicates that you should find out what they are due to because they are never present in normal urine. You might get a few red blood corpuscles from injury from the catheter if the patient happens to have a lesion in the sphincter urethrae.

I am glad that Dr. Pitts mentioned his case treated with four months of vesicovaginal fistula. From the fact that she failed to get well with this long drainage I should say that she probably belongs in this class of cases. My experience in treating badly infected cases with multiple ulcers, covered with incrustations, by making a drainage fistula and instituting irrigations has been a happy one. One exceptional case had the fistula about three years before healing, but I think eleven weeks was the longest any of the other cases required; you will see by reference to Case 5 that she had the fistula six months, with relief only as long as the fistula was open, just as in Dr. Pitts' case. If a woman were given the choice between a fistula, with its disagreeable consequences for four to six months and the two operations of making and closing the fistula, she would probably choose the slightly more extensive operation of excision with prospects of being well in a month.

Dr. Cabot has just asked me whether there are extensive blood vessel changes in the microscopic specimens. There is a considerable increase in vessels in some of the ulcer areas and an increase in the number and size of the vessels in the mucosa immediately surrounding the ulcer. The vascular changes are not excessive and the microscopic picture corresponds with what one would expect from the comparatively slight changes in the cystoscopic picture.

Dr. Cunningham has rightly said that the psychology of the nervous woman puzzles us all, but it is one of the most real things I have seen in surgery to see the change in the patient's expression after these operations. One patient said she had not realized what a general nervous tension she had been on for years and she was afraid to leave the city after leaving the hospital, dreading that her bladder trouble might return. Dr. Cunningham asks about the bacteriology. As I stated, if I found bacteria in the urine of any similar cases, I would not place them in this class but would consider them as belonging to the ordinary infectious type of bladder ulceration.

Dr. Clark asks about the comparative value of the Nitze and Kelly methods of cystoscopy. I have discussed this point rather fully in the text, giving my reasons for preferring the Kelly method in these cases which show comparatively slight mucous membrane changes.

DISCUSSION OF DR. CROSBIE'S PAPER.

DR. J. H. CUNNINGHAM, JR., Boston: Dr. Crosbie's paper interests me very much as I have been doing and advocating this operation since 1906, during which time I have done well over 100 cases. I cannot understand why this operation of drainage of an infected epididymis does not appeal more generally to surgeons. Apparently it does not, but I think that it should, as it is simply applying the principles of drainage to an acutely infected structure with the same beneficial results here as in other structures elsewhere in the body.

In some cases I have taken small pieces of the

iseased epididymis for pathological study. In the early stages of the disease the ducts are distended with polymorphonuclear leucocytes, and among them are also phagocytic endothelial leucocytes. In places the lining epithelium is destroyed and the exudation is continuous with an extensive infiltration of the connective tissue spaces about the tubules.

In places the tissue has been destroyed and dissolved so that small abscesses exist. At the periphery of the acute process there is some infiltration with lymphocytes and some fibro-blasts. Within some of the leucocytes are flattened diplococci, which are Gram negative.

In the later stages of the disease the intertubular connective tissue is much increased and contains leucocytes and gonococci, both intra- and extracellular. Such a pathology should argue for drainage. We are all sure that recurrences of epididymitis are not uncommon and I have found the gonococcus in the epididymis eight years after the infection.

In regard to certain observations associated with the operation. In practically all the cases that the material from the punctured epididymis had been examined, eighty per cent. show growth of no other organism than the gonococci and in the remaining twenty per cent., pus without the organism. The urethral discharge, as a rule while it returns, is not so severe, and we believe that in some cases the disease in the other organs has been shortened by the operation. Of course the vesicles and prostate must retain the product of inflammation and must be treated. The operation is simply an operation on the epididymis and the prostate and vesicles must be treated afterwards. I have employed the Belfield operation together with epididymotomy in our cases, and they did not do any better than when epididymotomy was employed alone.

The subject of sterility has come up. I have had eight bilateral cases, six of which showed spermatozoa following the operation. One case showed tuberculous plus a gonorrheal process on one side. There are no reliable statistics on the subject of sterility following bilateral epididymitis, but the much quoted statistics of Burla have created the impression that sterility results in about forty per cent. of such cases. Dr. Crosbie says the number of operative cases are very small, but the percentage of cases not sterile following operation is not larger at any rate than those not operated. In fact, the evidence, such as it is, favors operation in preventing sterility.

Now in regard to the technic of the operation. There is nothing to add other than the fact that I believe that the scrotum should be opened and the fluid of the secondary hydrocele allowed to escape. I do not believe in puncturing the epididymis from behind and leaving the hydrocele fluid. The epididymis is punctured from within the tunica vaginalis, and I always squeeze the epididymis after doing it to express as much of the inflammatory product as possible. The puncture goes through the fibrous capsule, and the rest of the investigation of the epididymis must be done with a probe so as not to sever the tubules.

The one feature to which I wish especially to call your attention is the closing of the scrotal wound. I have employed this method of closing the scrotal wound for several years, not only in connection with epididymotomy, but in all operations upon the

scrotum, and I have never had a post-operative hematoma or ecchymosis. Bleeding into the lax scrotal tissues is certain to occur if the cut edges of the dartos are allowed to retract and are not again recovered and sutured. I have found that catgut is not well taken care of in the scrotal tissues and for these reasons I devised the following procedure, which has proven most satisfactory. Two mattress sutures of silkworm gut are passed through all the layers of the scrotal incision on both sides of the wound and tied over a rubber tube on either side of the incision. The two tubes thus serve as a clamp, extending the length of the incision. The skin edges are then united by a subcutaneous silkworm gut suture. These tubes are removed in 24 hours, having served their purpose of controlling hemorrhage and adhering the tissues.

To conclude, I think this operation, if judged simply by the postoperative results, is to be recommended. There is certainly no pain after the patient recovers from the anesthesia. There is a rapid drop of temperature, and the leucocytosis, which is often high, goes down very rapidly, and the patient recovers and returns to his work about five times as rapidly as by the expectant form of treatment.

Dr. H. BINNEY, Boston: There is a sub-class in this group of cases, in which I think an operation should be done under such circumstances as Dr. Crosbie has done it. This is the class where the infection is entirely in the globus minor. The bacteria seem to stop there, and do not cause inflammation in the globus major. The operation is so simple that it is particularly desirable, and consists of making an incision down to the globus minor, puncturing it, and in some cases incising it, where a considerable amount of pus comes out. In one case there was as much as a drachm, and in that case a drain was put into the cavity.

Dr. Thorndike has done that in a good many cases, and following him I have found it very satisfactory and prompt in relieving symptoms. It seems to be just as effective as doing the more radical operation. I have not done it in any cases where there is a large amount of hydrocele. In those cases I believe in a more thorough operation.

Dr. L'ESPERANCE, Boston: In the after-treatment of these cases I am sure the patients would be more comfortable if the Alexander bandage was employed rather than the T-bandage, such as Dr. Crosbie has described. This bandage has the advantage over the T-bandage in that it holds the dressing firmly in place, and does not have to be removed for care of the bowels.

Dr. H. CABOT, Boston: I want to point out what seems to me the strength of Dr. Crosbie's contribution this evening. It is that these cases may be operated upon in a dispensary service, not in hospitals. You simply cannot get beds for them in the hospital.

Dr. Crosbie has done that which I, for one, would not have had the courage to do. The cases have come to us in the out-patient, and we have referred them to the house, with the full knowledge that they would not get in. I knew it to be futile.

Dr. Crosbie has had the courage of his convictions, and has done the thing, and it satisfies me that we can now manage these cases, as we believe they ought to be managed.

I am quite with Dr. Cunningham in his view that this is the best method, but we have not had the

courage to apply it, until Dr. Crosbie shows us how to do it.

DR. A. RILEY, Boston: One of the best "boosts" that we have for this operation is the testimony of those who have had it performed. The other day I operated at the Dispensary on a colored man who hesitated a long time. I finally turned him over to the patients who had been operated upon. There were five on the seat at the time; they all got around, advised operation and convinced him.

This case had had acute symptoms for three days, and I found a pus cavity as large as the end of the ring finger in the globus minor.

Closed by DR. CROSBIE: I was very glad to get Dr. Cunningham's additional bilateral cases. Of course the question of sterility is certainly important. It is interesting to note that at the time Dr. Cunningham published his paper he had six bilateral cases, four of which were not sterile; now the number is up to eight cases, six of which are not sterile.

With regard to the method of closure, we have not had the slightest trouble with hematoma in any of our cases.

Book Reviews.

A Nursing Manual for Nurses and Nursing Orderlies. By DUNCAN C. L. FITZWILLIAMS, M.D., Ch.M., F.R.C.S. London: Henry Frowde, Hodder and Stoughton. 1914.

This volume in the series of Oxford medical publications is a very timely presentation of Red Cross methods and routine by a British surgeon, Captain of the first City of London field ambulance. The subject of first aid on the battlefield is fully dealt with and should prove of great value to any who are, or may hereafter be, engaged in such service in war. The book is so arranged that the consideration of the common diseases and injuries is associated with the anatomic and physiologic description of the regions and organs concerned. It is well illustrated with 106 text figures and forms an exceedingly convenient and practical pocket manual.

A Doctor's Viewpoint. By JOHN BESSNER HUBER, A.M., M.D. New York: Gazette Publishing Company. 1914.

This volume consists of a series of twenty-eight brief essays on medical and other topics, some of them reprinted from various medical and lay publications. They are in the author's familiar characteristic style, but can hardly lay claim to the literary merits of the greater medical essayists. Perhaps the comment and criticism on an antivivisection play are, at the present, the most timely and satisfactory items in this collection of miscellanea.

Obstetrical Nursing. By CHARLES SUMNER BACON, Ph.B., M.D. Philadelphia and New York: Lea and Febiger. 1915.

This volume in the Nurses' Text-book Series is somewhat ambiguously termed in its subtitle, "A Manual for Nurses and Students and Practitioners of Medicine." Like many books of its type, it attempts too much and between two aims fails in its fullest accomplishment. It is true that the physician should be familiar with the details of obstetric nursing, but it is better that he should acquire this knowledge from a text-book purely of nursing than that unnecessary details of medical knowledge should be incorporated in a nurse's text-book. Barring this criticism, the book is, in general, highly to be commended. It is clearly and effectively written and well illustrated with 123 engravings. If pruned of unnecessary medical items it should make an exceedingly useful manual for obstetric nursing.

Infantile Paralysis in Massachusetts, 1907-1912. Boston: Wright and Potter. 1914.

This belated report consists of a series of nine articles, some of them reprinted from other publications, dealing with the occurrence of epidemic poliomyelitis in Massachusetts during the quinquennium from 1907 to 1912, together with reports of special investigations in 1913 bearing on the etiology of the disease and the method of its transmission. A third of the volume is occupied by Dr. Sever's review of the recent literature of the disease with a selected bibliography of 141 titles. The volume also contains the work of Rosenau and others on the transmission of poliomyelitis by *stomoxys calictrants*; and the work of Lucas and Osgood on its transmission by virus from the nasal secretion. The volume is illustrated with a series of maps showing the distribution of the disease in Massachusetts in each year covered by the report and by another map showing the house distribution of the Springfield epidemic of 1912. The volume forms a valuable monographic record and history of poliomyelitis in Massachusetts during the period covered.

Medical Nursing. By A. S. WOODWARD, M.D., B.S. (Lond.), M.R.C.P. (Lond.). New York: Longmans Green and Company, London, Edward Arnold 1914.

This brief British text-book of nursing deals conveniently with general nursing procedures and with the special diseases grouped according to the visceral systems or regions involved. There are excellent chapters on massage and invalid cookery and an appendix on first aid treatment of emergencies. The book is illustrated with 68 text cuts and should prove a useful manual for nurses in both hospital and private work.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p.m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

JUDGE BAKER AND THE JUVENILE COURT.

THE sudden and early death of Judge Harvey C. Baker of the Juvenile Court has brought to public attention a life and an institution that have meant a great deal to this community. To the medical profession the event has special significance, for the work of the Juvenile Court has had much more in common with medicine than with the law, and it is probable that Judge Baker was more frequently in consultation with doctors than with lawyers in regard to his protégés. He saw in the crimes for which the children were brought before him, merely the expression of a diseased condition of the mind, which it was his duty to diagnose and, if possible, to trace out and remove the cause. His courtroom was like a physician's private office, and the children came to him just as a sick or injured child might come to a physician. Respect and kindness were the chief characteristics of

his manner with children, and they responded by showing their respect for him and giving him their confidence. Talking with the children themselves he could often trace out the causes which had led to their wrong-doing, for example, the influence of bad companionship, and by methods similar to those used by physicians in the treatment of morbid mental states, he was able to strengthen their resistance to temptations and to put them on their guard against influences which had resulted in their wrong-doing. The effects of these talks were reinforced by subsequent interviews with the judge and by an efficient follow-up system by probation officers, who worked with the same spirit as their chief.

The question was constantly presenting itself before the court: is the child's wrong-doing merely the result of its environment, or is it an expression of feeble-mindedness. The feeble-minded child is often attractive in appearance, and the condition can only be detected by tests carried out by those with special training. Judge Baker attached great importance to the medical examination of many of the children who were brought to him. A number of prominent neurologists assisted him in this work, and the Psychopathic Hospital, since its establishment, has been a great help. Judge Baker was especially interested in this phase of the work and was one of the founders and president of the Massachusetts Society of Mental Hygiene. He frequently called attention to the waste of effort and the great danger to the community in trying to help the feeble-minded child by the same methods that are used for the child of normal mental development. The feeble-minded child should be in a suitable institution for his own protection, for the protection of society, and to prevent his transmitting his weakness to offspring. The feeble-minded with criminal tendencies are an especial menace to the community. The Juvenile Court, by the early detection of cases of this class, saves society from their lowering and degrading influence, and does real preventive medical work of the highest type. We are just beginning to realize that with the problem of the feeble-minded is bound up the future of the human race.

It is perfectly evident to our profession what vital and fundamental work this is and how great is the need of its extension. The Juvenile Court has jurisdiction over only a small propor-

tion of the delinquent children of Boston—those living in the central district. In the other sections of the city and in the other cities of the Commonwealth there are the same problems and the same need for the sort of work Judge Baker was doing. The Boston Juvenile Court has thus been a sort of experiment station, on the success of which a great deal has depended. How great that success has been many have testified to since Judge Baker's death. To his co-workers and to those connected with the child-helping societies, his loss has seemed a staggering blow which threatens to check a movement of vital importance. The injury to this work would be incalculable should some one be appointed as judge who, instead of continuing the progressive methods of Judge Baker, should allow the court to revert to the ordinary type. Governor Walsh has a great responsibility in choosing a successor to Judge Baker, and in making his choice he should have the help of those who appreciate the importance of this work, among whom should be the medical profession and those connected with the child-helping societies.

While few have appreciated the features of the work to which we have referred, an unusually large number of our citizens have realized the unselfish devotion and public spirit which Judge Baker put into his work. They saw a life of extreme purity coming into the closest personal relation with children whose lives had always been darkened, shining upon them out of the warmth and kindliness of his heart, reaching out to them a helping hand and raising them up by the sheer strength and beauty of his own character. Those who can also see in Judge Baker a leader in a great movement for the benefit of unfortunate children which is to raise the moral standard of the whole race, have a picture of human service, the equal of which it is hard for us to conceive. The only possible memorial to such a life of service is the extension of the work to which he was devoted.

PROPOSED PROFESSORSHIP OF PSYCHIATRY.

IN the issue of the JOURNAL for April 15 we published an appeal made by Dr. William N. Bullard, Dr. Walter Channing and Dr. Herbert B. Howard for subscriptions to a fund

which they desire to raise for the establishment and endowment at the Harvard Medical School of a professorship of psychiatry or mental diseases. A further statement of the aims and purposes of this proposed endowment has recently been issued, pointing out the increasing menace of insanity to this country and the immense cost of its care to the community. It is believed by the proponents of this professorship that the remedy lies in the more thorough investigation of mental diseases with a view to their prevention.

"If insanity is to be prevented or cured, its causes must be understood and the earliest symptoms recognized. The physician is the one to do this, but hitherto he has known little or nothing of the subject. His education in this respect has been sadly deficient. This should no longer be the case and need not be, provided the medical student receive adequate instruction.

"To accomplish this object, there should be an endowed chair of mental diseases, or psychiatry, in the Harvard Medical School, filled by a professor who could devote his whole time to teaching and conducting clinics. Every student should be so well grounded in his knowledge of the causes and development of mental diseases that he could return to his own community a teacher himself and a leader in the investigation of the causes responsible for mental defect or breakdown. This connection between instruction and research is so intimate that the former may be said to be based upon the latter. Hence the research work in the Neuropathological Department forms the basis and foundation for instruction in insanity and mental disease, and its proper support is necessary in order that the instruction may be of the highest grade. When it is realized how far-reaching its results would be in the improvement of the health of the people and in the saving of money, it appears evident that no department of a medical school is more important than that of mental diseases, which eventually should become one of preventive medicine."

Massachusetts has already made an important beginning in the prophylaxis of mental disease by the establishment of the Psychopathic Hospital in Boston, which is already closely affiliated with the Harvard Medical School. It would seem that friends of the school could not better show their loyalty to it, their interest in medical research and their service to the community than by making possible the establishment at the school of such a professorship of psychiatry to complement from the didactic side, the work of psychopathic study and progress. Contributions to the fund for this proposed chair should be sent to Dr. Herbert B. Howard, in care of the Old Colony Trust Co., 17 Court St., Boston.

FLY SUPPRESSION.

THE important part played by insects in the transmission of many diseases is now well established, and, indeed, is rapidly assuming larger proportion, so that more and more diseases are embraced in their operations. On the other hand, there has been an unwholesome tendency to associate certain insects only with the transmission of certain diseases. This idea is a fallacy. An insect may carry many disease organisms and should not be credited with great selective powers. In this way it is that the common house fly has been misnamed the "typhoid fly," on the belief that it is solely concerned with the transmission of typhoid, although it is an agency in other intestinal conditions and in tuberculosis. The house fly is merely the mechanical carrier of the bacillus typhosus from infected material to food, or even more directly—from infected material to victim. The house fly does not act as a host in the sense that it retains the bacillus within itself to transfer to individuals with whom it comes in contact. To confound the house fly solely with typhoid fever is to give a false sense of security with respect to that insect. On the other hand, the large stable fly is yet distinctly associated with the spread of poliomyelitis, which disease it is believed to transmit to human beings through its bite. But this does not mean that it cannot carry other diseases mechanically, as does the house fly.

It can be seen that the suppression of the fly is a very important factor in the public health. Various agencies, realizing the potency for evil of this insect, have carried on fly suppression campaigns. But because of the prolificity and universality of distribution of the fly, no great progress can be made in its destruction or suppression. As everywhere, it is prevention before conception rather than suppression thereafter which gives the largest hope of success.

The logical time for prevention-suppression is not during the period of mature existence and activity—during the summer—but in the spring, before the fly has had time to breed and develop. During the winter only a few adult flies survive in cellars and barns. Flies are subject to a great many conditions which make their mortality very high. As soon as warm weather sets in, the survivors begin to lay their eggs in manure, piles, garbage or other organic refuse. And it is in these places that a thorough spring cleaning

would destroy the few adults and put them without the possibility of breeding.

It is to be remembered that it takes ten days for the development of the fly from egg to *imago*, and the mature fly, with its immense breeding possibilities, can at all times be anticipated by the removal and the destruction of all organic refuse at least once in ten days—the period of development. In the case of valuable organic matter, as, for example, manure, proper protection from fly contamination should be enforced. All organic refuse should be covered and protected in one way or another until final disposal. This method is the only sure one, the cheapest, and the one that requires the least amount of expenditure of energy. In view of the fact, however, that such protection is likely often not to be obtained, the employment of some simple form of trap may often be desirable in conjunction with other measures. In another column of this issue of the JOURNAL is presented a brief description of such a trap, approved by the United States Department of Agriculture. As, in the case of the prevention of typhoid fever neither protective inoculation nor the purification of water supplies should be solely relied upon, so, in the extermination of the fly, reliance should, at present, be placed on no one measure, but upon a judicious combination.

PROPOSED TRANSFER OF NEW YORK QUARANTINE.

ON April 20, a meeting was held at the New York Academy of Medicine for the discussion of the subject of transferring the quarantine service at the port of New York from local to federal control. The public health committee of the Academy of Medicine strongly approves the proposed transfer, and in accordance with its opinion, prepared the following series of resolutions, which were signed by a number of organizations and individuals in New York and elsewhere, and were adopted at the meeting in question.

Whereas, Maritime quarantine, like over-sea commerce, is not a matter of local but of national and international interest and importance; and

Whereas, The modern tendency in quarantine administration all over the world has been from local to national and international rules and regulations which insure uniformity of system and practice; and

Whereas, Quarantine work is essentially scientific in its nature, and cannot be carried on effi-

ciently unless the tenure of office be independent of changes in administration and of politics; and

Whereas, The United States Public Health Service, by its organization, the character, training and experience of its personnel and its opportunities for constant communication with all foreign ports, is admirably equipped to administer quarantine in a most efficient manner as attested by the satisfactory results obtained in San Francisco, New Orleans, Mobile, Manila, and the 50 or more other stations administered by the Service in the United States and its dependencies; and

Whereas, The history of local quarantine, including that of the port of New York, has shown that in times of crisis the local stations have been unable to cope with the situation without the assistance of the Federal Government; and

Whereas, There exists in Europe at the present time widespread quarantinable disease, which will become a source of grave danger to this country when immigration resumes its usual course at the termination of the war; and

Whereas, the opening of the Panama Canal will bring New York into direct shipping contact with South American and Asiatic countries, thus increasing the possibilities for the introduction of endemic tropical diseases; and

Whereas, Of all ports of this country, that of New York ranks first as a receiving station for foreign goods and immigration, as well as a distributing center for the entire country; and

Whereas, The federal government controls all the services incident to the administration of the port of New York, with the single exception of the quarantine, which is logically a part of the immigration service; and

Whereas, The United States as a party to international quarantine agreements, cannot guarantee their uniform observance unless all quarantine stations are under federal control; and

Whereas, The expenses for health protection, the benefits of which are shared by all parts of the nation, should not be borne by one city or state; and

Whereas, All the ports of this country, with the exception of Baltimore and New York, for the reasons above cited have already ceded their quarantine functions wholly or in part to the federal government;

Therefore, Be It Resolved, That the economical and efficient administration of the quarantine service, and above all, the safeguarding of public health, demand the transfer of the quarantine station of the port of New York from the state to the national government; and

Be It Further Resolved, That the governor of the state of New York be and hereby is respectfully and earnestly urged to take immediate steps to secure such transfer.

At the time recently when the same question was under consideration with reference to the quarantine service at the port of Boston the

JOURNAL advocated editorially the policy of placing such service in the hands of a uniform national administration. The same reasons which dictated this policy in Boston apply in New York with equal force; and in the interest of public health it is cordially to be hoped that the movement in New York for the transfer of the local quarantine may be successful, as it was in Boston.

EPIDEMIC OF STREPTOCOCCUS SORBI THROAT.

THERE has lately been prevalent in the Dorchester district of Boston and in the adjacent part of Milton, Mass., an epidemic of streptococcal tonsillitis, in some cases with metastatic complications similar to others which have prevailed a year or about this season during several years. On April 25 two hundred and ten cases had been reported in Dorchester and thirty-six in Milton. As on previous occasions, it has been strongly suggested that the disease has been disseminated through an infected milk supply; but at a season of prevalent cold and dusty winds the likelihood of air dissemination is, perhaps, equally possible. As a matter of fact, no decision has yet been reached, and conclusions should not be made until the forthcoming of the official report of investigation by a responsible board of health.

MEDICAL NOTES.

TWENTIETH ANNIVERSARY OF THE DISCOVERY OF THE X-RAY.—A meeting commemorative of the twentieth anniversary of the discovery of the x-ray was held at the New York Academy of Medicine, Hoosack Hall, on May 5, 1915, by the Roentgen Ray Association of Greater New York. The following addresses were delivered: "The Influence of Roentgen's Discovery on Physic Science," by Prof. Bergen Davis of Columbia University; "Roentgen's Discovery, Its Recent Developments and Future Possibilities," by William D. Coolidge, Ph.D., of Schenectady, N. Y.; "Historical Review of the Development of the X-ray Tube" (illustrated by lantern slides); by H. Clyde Snook, Ph.D., of Philadelphia, Pa.; "The Physical Characteristics of Roentgen Radiation with Reference to the Questions Involved in Treatment," by Professor J. S. Shearer of Cornell University; "The Inf

of Roentgen's Discovery on Medicine," by Ludwig Kast, M.D., of New York; "The History and Development of the Art of Roentgen Ray Diagnosis," by Percy Brown, M.D., of Boston.

ASSOCIATED OUT-PATIENT CLINICS OF NEW YORK.—The second annual report of the Associated Out-Patient Clinics of the City of New York is an interesting record of this attempt on the part of the dispensaries and out-patient departments of the hospitals of New York and Brooklyn to improve the character of the work done at those institutions by the formation of a society whose aims are stated as being: first, the coordination of the work of existing dispensaries and out-patient clinics; second, the elimination of unworthy applicants for treatment; third, the promotion of proper standards of treatment; fourth, the promotion of economy and efficiency in dispensary management. Forty hospitals and dispensaries in New York City are members of the association and twelve more hospitals belong to the Brooklyn chapter. Various committees report on the desirability of the establishment of whooping cough clinics, evening eye clinics, methods of dispensary accounting, uniform dispensary records, the statistical reports of dispensaries, occupational diseases and dispensary fees. Later results of the work of this association will, no doubt, prove the efficiency of these methods of coöperation on the part of the leading hospitals of a large city, in a department of its work which covers so extensive a field.

EXCEPTIONALLY LOW TYPHOID RECORD IN NEW YORK.—For the first time in very many years not a death was reported from typhoid fever last week. The only other week in the history of the department which was free from a mortality from this cause was the week of April 1, 1909. The number of deaths from this cause the week of April 25, 1914, was 6. This was the most noteworthy incident of the week's mortality. It is also worthy of note that there was not a death reported during the past week in the borough of Manhattan from homicide.

The wave of epidemic influenza which reached its culmination during the week ending April 12 is gradually receding, as shown by the mortality figures for the past week, during which there were 1748 deaths and a death rate of 15.71 per one thousand of the population reported as compared with 1637 deaths and a rate of 15.30 for the corresponding week of 1914, a decrease in the absolute figures of 111 deaths and in the relative figures of 63 deaths.

There were 28 deaths reported from influenza compared with 13 for the corresponding week of 1914, 200 deaths from lobar pneumonia as compared with 122, 228 deaths from pulmonary tuberculosis as compared with 186, 348 deaths from combined heart and kidney diseases compared with 335.

The mortality from measles, diphtheria and croup, and whooping cough, was considerably greater than in the corresponding week of last year.

The mortality of infants under one year was slightly below, while that between one and five years was somewhat in excess of, last year's figures. Between the age of 5 and 65, the mortality was considerably increased, as was the mortality at ages 65 years and over.

The death rate for the first 17 weeks of 1915 was 14.72 per one thousand of the population as against a rate of 15.46 during the corresponding period of 1914.

A study has just been completed to show the effect of the European war on the population of this city. Diminished immigration caused a decrease in the rate of growth ordinarily expected. This necessitated a revision of last year's mortality figures, from 13.40 deaths per one thousand as originally calculated to 13.48.

VITAL STATISTICS OF LONDON IN 1914.—Statistics recently published show that during the year the total birth rate of the city of London was 24.3 and the death rate 14.4. Among the several districts and boroughs the highest birth rate and death rate (32.1 and 19.6 respectively) were both in Shoreditch, a crowded east end slum. The lowest birth rate, 10.2, was naturally in the business district of London. The next lowest birth rate was 14, in the city of Westminster, a fashionable residential district. The lowest death rate was 10.7 in Lewisham, an eastern suburb along the Thames. The infant death rate under one year of age was also highest, 141 per thousand births, in Shoreditch, and lowest, 67, in Chelsea, a western suburb along the Thames. The total infant mortality of London was 104 per thousand births. Of the important infectious diseases phthisis caused 6810 deaths, infantile enteritis 3021, and measles 1,385. There were no deaths from smallpox in London during the year.

AMERICAN RED CROSS SENDS PHYSICIAN TO PAIGNTON, ENGLAND.—Dr. Herbert H. Howard, Harvard Medical School, 1912, has been appointed by the American Red Cross, to the position of staff physician in the American Women's War Relief Hospital at Paignton, South Devon, England. Dr. Howard sailed on the steamship *New York* May 1.

PREVENTION OF SMALLPOX AT MEXICO CITY.—It is reported that, to combat the spread of smallpox in Mexico City, a supply of vaccine was ordered from New York and was due to reach Vera Cruz on April 26, whence it would proceed by train to Mexico City. The State Department at Washington states that there is no epidemic of smallpox in Mexico City. There were apparently several cases there and these measures were taken to prevent the further spread of the disease.

DINNER OF HARVARD CLUB OF PARIS.—The Harvard Club of Paris held, on April 21, a dinner at which James Hazen Hyde presided. Members of the French Academy, of the Harvard faculty and representatives of the foreign office and of the Sorbonne were present.

Among those who spoke were United States Ambassador Sharp, Lucien Poincaré, brother of the French President; Emile Boutroux, professor of philosophy at the University of Paris; Eugene Brieux, the playwright; Dr. Harvey Cushing of the Harvard Medical School and Prof. Edwin H. Hall, professor of physics at Harvard.

NEW BUILDINGS AT WASHINGTON UNIVERSITY MEDICAL SCHOOL.—Washington University Medical School dedicated its new buildings on April 29 and 30. Addresses were delivered by Dr. Eugene L. Opie, dean of the medical school; Dr. William H. Welch, of Johns Hopkins University; President A. Lawrence Lowell, of Harvard University; Dr. William C. Gorgas, surgeon general, United States army; Dr. William T. Porter, Dr. R. J. Perry, Dr. George Dock, Dr. Abraham Flexner and President Henry S. Pritchett, of the Carnegie Foundation for the Advancement of Teaching.

TYPHUS SUSPECTED AT THE PORT OF NEW YORK.—A Greek steamer, the *Themistocles*, sailing from Piraeus, was held in quarantine on its arrival at New York and eighty-six passengers, suspected of having typhus were removed to Hoffman Island for treatment. There were 667 passengers on the steamer all of whom were subjected to a rigorous physical examination, and those showing evidence of infection were removed.

AMERICAN UNIT ON WAY TO SERBIA REACHES ITALY.—The unit of the American Red Cross detailed for work in Serbia, under the leadership of Dr. Richard P. Strong of Harvard Medical School, arrived at Brindisi, Italy, on April 21 and from there left for Saloniki, Greece, to route to Serbia.

Report from Nish states that Dr. Strong arrived in that city on April 24.

THE MAYO FOUNDATION FOR MEDICAL RESEARCH.—In the JOURNAL of February 18, 1915 (Vol. clxxi, No. 71, p. 271) mention was made of the \$1,000,000. endowment fund given by the Drs. Mayo of Rochester, Minn., for the establishment of a foundation for medical research to be under the control of the University of Michigan. The Minnesota Senate has passed a bill prohibiting this affiliation. It is to be hoped that satisfactory arrangements may be made so that the great benefit to accrue from such a foundation may not be lost.

AWARD OF THE GROSS PRIZE.—It is announced

that the Philadelphia Academy of Medicine has awarded the Samuel B. Gross Prize of \$1,500 for the year 1915 to Dr. John Lawrence Yates of Milwaukee, for his essay entitled "Surgery in the Treatment of Hodgkin's Disease."

ARREST OF MEDICAL IMPOSTERS.—Report from New York states that 43 medical imposters have been arrested. They were proprietors of so called free museums and those without licenses were charged with fraudulently practicing medicine. Those who were licensed were charged with prostituting their profession. It is believed that a chain of such medical offices connected with free museums are operated in Pittsburgh, Newark, Baltimore and a number of other cities.

EUROPEAN WAR NOTES.—Report from Mitylene says that in Erzerum, Armenia, and its surrounding district, there are one thousand deaths daily from smallpox and typhus which are extensively prevalent in that district, and in Trebizond.

It is reported that Sir William Osler of Oxford has proposed that the Harvard Medical School should send abroad in June for service at an English Government field hospital, either in France or in England, a second unit, to consist of twenty-four surgeons and to have charge of over one thousand beds. It is understood that this proposition is under serious consideration at the medical school. The first Harvard unit is now serving at the American Ambulance Hospital at Neuilly, France.

EUROPEAN WAR RELIEF FUNDS.—On May 1 the totals of the principal American relief funds for the European War reached the following amounts:—

	N. Y.	N. E.
Belgian Fund	\$1,028,924.80	\$254,466.40
Jewish Fund	652,983.56	60,448.61
Red Cross Fund	490,315.91	131,683.37
American Ambulance	386,417.80	
American Women's Hosp.	250,000.00	
Committee of Mercy.....	150,817.16	
Prince of Wales	119,011.08	
Polish Fund	52,115.25	44,712.39
Serbian Fund	48,263.25	15,815.25
Persian Fund	26,149.71	
Belgian Red Cross		10,890.00

NATIONAL CONFERENCE OF CHARITIES AND CORRECTIONS.—The preliminary program has been announced for the forty-second annual meeting of the National Conference of Charities and Corrections, which is to be held at Baltimore Md., from May 12 to 19. The program contains the names of over fifty physicians, charitable workers and penologists, and it is believed that contemporary conditions associated with the European War will contribute to make the meeting one of unusual interest and importance. A recently issued bulletin of the Massachusetts State Department of Health contains the following statement of the medical program.

"The field of health and hygiene is compre

ended in a series of discussions on health topics, under the chairmanship of Dr. Richard C. Cabot of Boston, and of social hygiene, under the chairmanship of Mrs. Martha P. Falconer, superintendent of the State School for Girls at Darling. Dr. Cabot's program will include an explanation of the newer methods of hospitals in their social service departments, the chief speaker being Dr. William H. Welch of Johns Hopkins Hospital, Baltimore, and a symposium on the social education of the physician, by Mr. Joseph Lee of Boston and Dr. Charles P. Emerson, dean of the medical department of Indiana University, Indianapolis. Mrs. Falconer's program will be addressed to the question, "How shall We Suppress Prostitution?" this following previous considerations at the National Conference of the extent of our scientific knowledge of this subject and the proper use of popular educational methods. Dr. Katherine Bement Davis, Commissioner of Correction of New York City, will give "A Survey of Educational Work," and other speakers will treat subjects such as protective league work, prostitution in rural communities, and methods of scientific investigation.

"The discussion of state care of the insane, feeble-minded and epileptic will occur under the chairmanship of Dr. Walter E. Fernald, superintendent of the Massachusetts School for Feeble-Minded at Waverley. It will include answers to the question, "What is Practicable in the Way of Prevention of Mental Defect and Disease?" and a discussion of "Available Fields for Research and Prevention in Mental Defect." The speakers in this section include Dr. Adolf Meyer of Baltimore, Dr. C. B. Davenport, Cold Spring Harbor, N. Y., Dr. H. H. Goddard of Meland, N. J., Dr. Martin W. Barr, superintendent of the Pennsylvania School for Feeble-Minded at Elwyn, and Dr. Walter S. Cornell of Philadelphia."

BOSTON AND NEW ENGLAND.

ANNUAL MEETING OF THE MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY.—At the annual meeting of the Middlesex South District Medical Society, held at the American House on April 2, the following officers were elected: Dr. William D. Swan of Cambridge, formerly vice-president, became president; vice-president, Dr. George T. Tuttle, Waverley; secretary, Dr. Lyman S. Hapgood, Cambridge (re-elected); treasurer, Dr. Charles A. Dennett, Arlington (re-elected); commissioner of trials, Dr. Lewis M. Palmer, Cambridge; and orator, Dr. Charles F. Painter, Newton. The new auditors are Dr. Nat. T. Shannon, Cambridge; Dr. Lincoln F. Sise, Medford; and Dr. Frederick G. Smith, Somerville. Dr. William C. Hanson of Belmont delivered the annual oration on the subject of "Scope of Public Health Service." Over one hundred members were present.

CASE OF RELAPSING FEVER IN BOSTON.—On April 23 a case of relapsing fever was discovered in an Armenian immigrant at the Boston detention station, where he had been retained since his arrival aboard the *Canopic* from Italy six weeks ago. The patient had been transferred to quarantine and the detention station is to be fumigated. Another case of this unusual disease was reported in Boston in 1909, and the only other one apparently recorded in this country occurred in 1872.

MEMORIAL TO DR. W. D. KELLY.—At the time of the death of Dr. W. D. Kelly of Boston, his numerous friends among the school children of the West End raised a sum of money to buy flowers for his funeral. A surplus of \$51.50 was given to the Milk and Baby Hygiene Association, in which he was much interested, as a memorial to Dr. Kelly.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending April 27, 1915: Diphtheria, 75, of which 5 were non-resident; scarlatina, 112, of which 14 were non-resident; typhoid fever, 2; measles, 219, of which 5 were non-resident; tuberculosis, 63, of which 6 were non-resident. The death-rate of the reported deaths for the week was 18.85.

Massachusetts Medical Society

EXCURSIONS TO THE ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION IN SAN FRANCISCO, JUNE 21 TO 25, 1915.

FELLOWS of the Massachusetts Medical Society have been invited by the Chicago Medical Society to join a special train party for San Francisco leaving Chicago, June 17, and arriving in San Francisco, June 21. The tour will be conducted by the Gregory Tours, 1103-4 Lytton Building, Chicago, and the rate from Boston and return, including all necessary expenses, hotel accommodations in San Francisco, will be \$188.20. To secure accommodations and for further information it is necessary to communicate with Dr. R. R. Ferguson, 3923 North Keeler Avenue, Chicago, Ill., as soon as possible.

Some of the fellows have signified their intention of making the trip to San Francisco by the McCann's Tour, which leaves Boston June 16 and arrives in San Francisco June 20. The expense of this trip is \$285, from New York and return on July 8, including two days in the Glacier National Park and a day at the Mayos' Clinic on the return journey. Information about this trip may be obtained from McCann's Tours, 1328 Broadway, New York City.

Miscellany.

PREGNANCY CLINICS.

THE following statement with regard to pregnancy clinics in Boston has been submitted by Dr. Arthur B. Emmons, whose article on "The Care of Prospective Mothers," was published in last week's issue of the JOURNAL:—

"Prenatal care is become prominent in the lay as well as in the medical press. The following statement as to the value and desirability of such care and the policy of carrying on prenatal clinics, approved by a representative advisory medical committee, may be of interest to the medical public as a new line of public health education. The Committee on Public Health of the Women's Municipal League of Boston, Mrs. William Lowell Putnam, chairman, has organized a sub-committee on Prenatal and Obstetric Care, composed of representatives of the Boston Dispensary, M. J. Davis, Jr., director; The Instructive District Nursing Association, Mrs. E. A. Codman president and Miss Mary Beard, director; Miss Strong of the South End House, and A. B. Emmons, 2d, M.D., physician-in-chief of the Maverick Dispensary. This committee recognize that such work is primarily medical and has, therefore, obtained the counsel of a medical advisory committee, whose statement follows:—

COMMITTEE ON PRENATAL AND OBSTETRIC CARE. STATEMENT OF THE MEDICAL ADVISORY COMMITTEE.

In spite of agencies which provide obstetric care for the poor there are today many women of limited means who do not receive reasonable, safe prenatal care, and no existing agency has provided for many of these women.

The preliminary examination and continued supervision of the prospective mother is recognized today to be a part of adequate obstetric care. This care is proved to be of value as a safeguard to the mother, an aid to maternal nursing, and a large factor in the prevention of infant mortality.

Prenatal and obstetric clinics are considered a means of meeting this need. The Committee on Prenatal and Obstetric Care of the Women's Municipal League of Boston has under its control three such clinics, and is ready to develop others whenever the need is shown. The work of this committee does not duplicate the work of other medical agencies, nor does it interfere with the doctors in the vicinity.

GENERAL PURPOSES.

1. To offer prenatal care, *i.e.* the early examination and supervision of prospective mothers of limited means.

2. To coöperate with private physicians, or, where, necessary, to provide experienced ob-

stetric service to insure prenatal and post-natal nursing care.

3. To teach prospective mothers general hygiene and the importance of medical supervision during pregnancy, and of adequate care at confinement.

A preliminary medical and obstetrical examination made as early in pregnancy as possible is valuable in forestalling dangers, in preventing accident, and in providing intelligently for the pregnancy, the confinement, and the care of the baby.

The nursing service should include the presence of a nurse at the clinic during the preliminary examination, visits in the home at intervals sufficiently frequent to prevent unforeseen complications, and as frequently as required in cases presenting abnormal symptoms, also the usual nursing during the puerperium.

- - -

CLASSES OF PATIENTS TO BE RECEIVED.

This service is designed to reach all those of limited means, to whom the usual fees for an equally efficient service would be reasonably considered a hardship.

FEEES.

The preliminary examination at the clinic and the supervision of pregnancy by the committee's obstetrician is paid for by the Women's Municipal League in order to develop the work as a measure of public health. No charge is made, therefore, to the patients for this service. A fee of \$10.00 is charged for the obstetrical care at confinement. The nursing fees are the usual ones of the Instructive District Nursing Association which provides the entire nursing service.

RELATIONS TO LOCAL PHYSICIANS.

Any physician may refer to our clinics a patient for prenatal care only, if he so desires, and such patients will be given examination and nursing supervision during pregnancy, and will be returned for obstetrical care to the physician who referred them, with information of conditions found. Doctors in the neighborhood of any one of our clinics are also invited to refer to us patients who are unable to offer the usual fee for adequate obstetric care. Persons who apply at the clinic, but who are found to have a family doctor to whom they are able to pay the usual fee, will be referred back to their physician. Physicians will always be welcomed at the clinics.

A SIMPLE TRAP FOR THE HOUSE FLY.

IN another column of this issue of the JOURNAL we have commented editorially on the importance of fly suppression and have referred to a description of a simple trap for the house fly, approved by the United States Department of Agriculture and described in its recent bulletin (No. 200). The experiments upon which the invention of this trap was based, were conducted at the Maryland Agricultural College during August and September, 1914, and it is claimed that by its means at least 98% of breeding fly larvae are destroyed.

"The principle of the trap is simple, it is easy to construct, and the expense is said to be probably less in the long run than the investment which many farmers now make in screens for their dwellings, and sprays and fly-nets for their live stock. In its roughest outlines the trap consists of a concrete basin with a latticed wooden platform erected upon it to hold the manure. The basin is connected by a drain pipe with a small concrete cistern. The bottom of the basin is filled with water, into which the maggots breeding in the manure drop, as they are about to turn in the pupa or ehrysalis stage, and are drowned. At frequent intervals the water is run off into the cistern and is then pumped back on the manure pile. In this way all the liquid manure is saved.

"The successful operation of this trap rests upon several facts connected with the habits of the house fly which have been thoroughly established by observation. The adult fly lays its eggs in fresh manure. There they remain until the larva stage is almost over and the insects are about to enter the pupa or ehrysalis stage. At this time a pronounced tendency to migrate is evident. In consequence, if the manure is placed upon a platform with a latticework bottom, the larvae, while migrating, will fall through these openings into the water in the basin below. In the case of the experiments at the Maryland Agricultural College a careful count showed that between July 25 and Oct. 1 about 112,000 larvae were killed in this way. This, however, does not include the number that were picked up from the basin by sparrows or poultry. Altogether it is estimated that during the warm weather the efficiency of the trap was probably 99%. Later, when the temperature was lower, the trap's success was not so marked. This was accounted for by the fact that when the air is much colder than the manure heap the larvae will not attempt to leave the heap and therefore will not fall into the basin.

"Another difficulty experienced arose from mosquitoes using the water in the basin and the cistern to breed in. This was overcome by cleaning out the basin at regular intervals and by sprinkling a little oil over the surface of the water in the cistern.

"Properly constructed, such a trap offers no obstacles to the convenient and economical

handling of manure. It is essential, however, that each day's addition to the heap should be sprinkled with sufficient water to keep the manure moist but not enough to cause leaching. The details of the construction of the trap are contained in the bulletin already mentioned. This particular trap was designed to hold the manure produced by three horses for three months, but there is no reason why larger quantities should not be treated in the same way, by building larger traps or by building several of smaller size."

Correspondence

THE AMERICAN WOMEN'S WAR HOSPITAL.

(From Our Special Correspondent.)

30 FINSBURY PARK ROAD,

LONDON, N., April 13, 1915.

Mr. Editor: The most interesting hospital which I have visited in England is The American Women's War Hospital at Paignton. It is over a month since my visit and I went there as a guest, not a reporter.

Paignton is a winter resort in Devon on the southern sea coast. Mr. Singer's estate on the outskirts has been transformed into a hospital. It is a beautiful place surrounded by well-kept grounds and overlooking the sea. A remarkable tropical garden filled with palms, century plants and other delicate vegetation bears testimony to a mild health-giving climate.

In the Singer home itself are several wards, an excellent operating room and quarters for the fifty odd nurses. As the house is rather extravagantly furnished, a group of "Tommyes" in blue flannel suits and bed slippers made a rather strange picture as they knitted or played cards in the stately drawing room. When one man, fresh from the trenches, was being carried in for the first time, he looked at the statues about him and up a flight of marble stairs to a huge painting of the Marriage of Napoleon and ejaculated, "My word, is this Windsor Castle?"

An arena planned for indoor-riding has been transformed into an excellent, large ward. After the other lights are out the rays of two dark lanterns illuminate a large British flag high above the beds. Several other outhouses are used as wards and a building which covered a swimming pool is being prepared in anticipation of a greater influx of wounded with the coming of warm weather.

The colony of eight American doctors is very pleasantly housed. A stranger is immediately made to feel the atmosphere of American friendliness and good cheer. Their only complaint seemed to be that the cases received were not severe nor varied enough. A surprisingly large number of them were cases of frost-bitten feet. The nurses are mostly Americans, but there are a number of English and some Australians. A little English probationer told me that she had tried a number of English hospitals but found they needed no one, so she felt very fortunate to have been taken in here.

The soldiers seemed quite grateful for the care they were receiving. A Scotchman was weaving crossed American and English flags from colored yarn, and I found out later that it was a pair of bed slippers intended for his nurse.

The wounds of some of the men who had lain in hospitals in France for some time showed the usual results of neglect. One easily gets the impression that the Tommyes are longing to return to their regiments. I heard one of them express what appeared to be his true feeling on this subject. A kindly, old lady asked him if he was anxious to get back to fight for his king and country. He looked at her a

moment and then said, "If you was out of hell on leave would you be anxious to get back again?" The speaker was a boy of 19 who had lain between the trenches, wounded, for three days.

Before leaving Paignton I had the good fortune of seeing a trainload of wounded arrive. The townspeople were outside the station with motors and wagons of all descriptions. Boy scouts and men in firemen's uniform were waiting to help with the unloading. The train came in with about 70 wounded. In a surprisingly short time they were carried out to the line of waiting vehicles and borne, through a crowd of villagers who occasionally broke into cheers, to the hospital on the hill.

I have been informed that the patients are taken from the base hospitals in France or direct from the firing line, carried over the channel in hospital ships and loaded onto trains waiting at the dock. All other traffic is held up to let these trains go through to hospitals in various parts of England and Scotland. Two days after the battle of Neuve Chapelle many of the wounded were resting in hospital wards on this side of the channel.

The trains mentioned above have all been fitted up since last August. The cars present quite a finished appearance, however. They originally carried milk. Now each one is painted white inside and a line of upper and lower bunks, swung from each wall, somewhat after the plan of an American Pullman sleeper. Straps are suspended over each bunk so that the patient may help when being moved about. As each man is removed his bed is folded up against the wall. In one car is a small operating room which appeared quite well equipped for use in case of emergency. The doctor in charge, together with his corps of assistants and orderlies, lives on his train during its trips back and forth. Sincerely yours,

WILDER G. PENFIELD.

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING APRIL 24, 1915.

7048 Jenkins Arcade Bldg.,
Pittsburg, Pa.

CENSORS' EXAMINATION.

The Censors of the Suffolk District Medical Society will meet to examine candidates for admission to The

Massachusetts Medical Society at 8 The Fenway, on Thursday, May 13, 1915, at 2 P.M.

Candidates, who must be residents of the Suffolk District, or non-residents of Massachusetts, should make personal application to the Secretary, and present their medical diplomas, at least three days before the examination.

For further particulars, apply between 2 and 3 P.M.

WALTER C. HOWE, M.D., *Secretary*,
303 Beacon Street

SOCIETY NOTICES.

THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. The eighteenth annual meeting of the American Gastro-Enterological Association will be held in Osler Hall, Medical and Chirurgical Building, Johns Hopkins University, Baltimore, Md., on May 10, 1915.

Physicians are cordially invited.

FRANKLIN W. WHITE, M.D., Boston,
Secretary.

NORFOLK SOUTH DISTRICT MEDICAL SOCIETY.—Annual meeting, United States Hotel, Boston, Thursday evening, May 6, 1915.

Business meeting at 6 P.M., followed by banquet and annual address by the president.

F. H. MERRIAM, M.D., *Secretary*,
South Braintree, Mass.

NORFOLK DISTRICT MEDICAL SOCIETY.—The sixty-fifth annual meeting of the Norfolk District Medical Society will be held at the New American House, Hanover Street, Boston, at 5.30 P.M., on May 11, 1915. The annual dinner will be served at 6.30 P.M.

The treasurer will be at the meeting ready to receive the annual assessment of \$5.00. All members are urgently requested to pay at that time, or to forward the amount to him, instead of making payments at the meeting of The Massachusetts Medical Society in June.

G. H. FRANCIS, M.D., *President*,
BRADFORD KENT, M.D., *Secretary*.

APPOINTMENTS.

Dr. Thomas M. Gallagher of Newton, associate medical examiner of the seventh Middlesex country district, has been appointed surgeon to out-patient department at St. Elizabeth's Hospital.

Dr. Douglas Stanley has been appointed professor of therapeutics at the University of Birmingham, England.

RECENT DEATHS.

DR. GEORG JOCHMANN of Berlin has died recently of typhus fever contracted in one of the Russian prison camps.

DR. ARTHUR ERNEST GALE, who died on April 27 at Chestnut Hill, Mass., was born in Haverhill, Mass., in 1869. He obtained his preliminary education at the Phillips Exeter Academy and after studying for a year in Harvard College, entered the University of Chicago, from which he received his doctorate in medicine. After practising his profession in Chicago for several years he retired from medicine and returning to Massachusetts engaged in business for the remainder of his life. He is survived by his widow and by one son.

DR. DANIEL JOSEPH MEHEGAN, a Fellow of The Massachusetts Medical Society, died of diabetes mellitus at his home in Taunton, Mass., on April 2, aged 46 years. He was a graduate of the Taunton High School, and of the Harvard Medical School in 1894. He had practised in Taunton since that time. He leaves a widow and four children. At the time of his death Dr. Mehegan was one of the Censors of the Bristol North District.

THE CARE AND TREATMENT OF THE WOUNDED IN THE EUROPEAN WAR.*†

By RICHARD DERBY, M.D., NEW YORK.

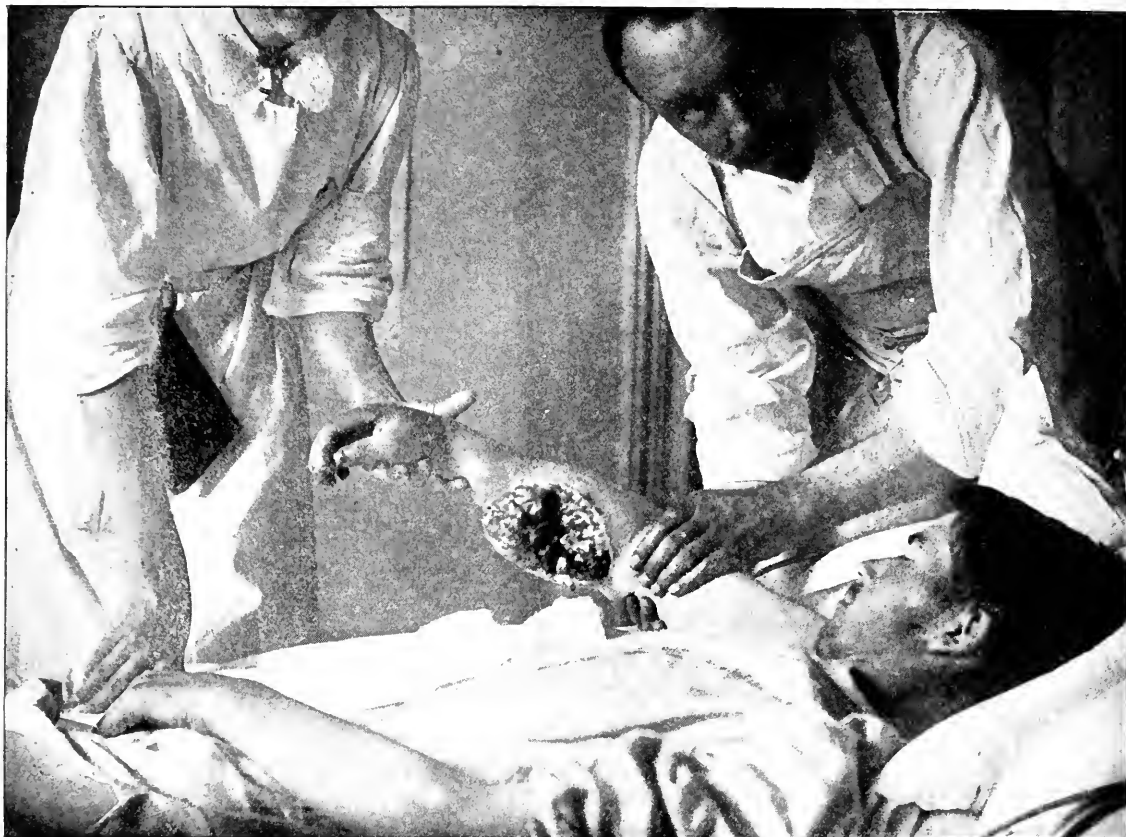

At the outbreak of the present European War, some of the Americans resident in Paris conceived the idea of establishing a Section for the Wounded, as an outgrowth of the American Hospital in Paris. The Lycée Pasteur, a large public school building nearing completion, was offered them for this purpose by the French Government. Prompt and efficient organization converted this building, in the short period of three weeks, into a modern and well equipped hospital, capable of caring for upwards of a hundred patients. With the nursing staff of the American Hospital as a nucleus, an efficient nursing department was organized by the addition of American and English volunteer nurses and resident American ladies in Paris. Many of the American business men of Paris volunteered as orderlies, ambulance drivers, and stretcher bearers. The doctors in attendance at the American Hospital, under the leadership of Dr. DuBouchet and Dr. Blake, took over the wards. The manager and his wife, of one of the large Paris hotels, volunteered their services to look after the cuisine. The actual administra-

tion of the hospital was in the hands of the surgeon-in-chief and a committee of the trustees of the American Hospital.

Early in September the hospital was ready for the reception of wounded. At that time, during the Battle of the Marne, no wounded were being sent to Paris. The city was in danger, under military rule, and the wounded were being sent to the south of France. One night, at the instigation of the Ambassador, a party of automobiles went out to Meaux, picked up from the battlefield and roadside all the wounded they could carry, and brought them into the hospital. Shortly after this, permission was given the ambulances of the hospital to remove wounded from the trains as they stopped at Auber Villiers and Ville Neuf St. George. Doctors always accompanied the ambulances to these stations, and saw to it that only the most serious cases were removed and brought to the hospital. The custom had been for an officer of the Santé to pass through the train at the stop near Paris, and ask if anyone complained and would like to be taken off. The question did not as a rule elicit an answer from the unconscious man with a fractured skull, while he with some trivial injury might avail himself of the invitation.

At the time of the Battle of the Marne the emergency and the number of the wounded was so great that the handling of them was a matter of the greatest difficulty. The French were then fighting a battle, the importance of which cannot be exaggerated. All the railroads and roads leading up to the line of battle, were primarily needed for bringing up reinforcements, ammunition and food. The moving back of the

* Read at a meeting of the Harvard Medical Society, Feb. 2, 1915.
† In another column of this issue of the JOURNAL is published a communication from Dr. R. B. Osgood which should be read in conjunction with Dr. Derby's article to obtain a complete picture of the history and present status of the American Ambulance Hospital.

Shrapnel Wound on Ventral Aspect of Forearm.

[By Courtesy of Dr. Samuel G. Underhill, of Lynn.]

wounded had to be relegated to fourth place, in order of importance. The trains going up, after unloading, were filled with wounded, and started on their return journeys. Economically, it was better for these trains to return to points in the south of France, from where they came, and not touch at Paris. The result was that the return journey was a long and constantly interrupted one. Long hours of waiting on sidings, while the supply trains passed north, turned the usual journey of part of a day into a week's length. In the early days of October, when I reached Paris, we received wounded at the hospital who had been a week in coming from points as near as Arras or Soissons. Military necessity was the explanation, and I know of no method, in face of the conditions, which could have brought the wounded more quickly to a base hospital at a safe distance.

During the early weeks of October, we received comparatively few wounded at the hospital, and this in face of the fact that spirited fighting was going on at this time. The French communiqués reported favorable progress. At first it was difficult to explain the discrepancy, but subsequent developments showed that during this period the Germans had been advancing, and had consequently been picking up the French wounded.

President Poincaré and General Gallieni, the

Military Governor of Paris, visited the hospital in the middle of October, and expressed their satisfaction and appreciation of the work being done there. There followed a promise from the French Government to send ten wounded a day to the hospital, which was strictly adhered to.

On my service of one hundred beds, there were 82 cases of shrapnel wounds, 20 cases of rifle bullet wounds, and one bayonet wound. The shrapnel wounds were, without a single exception, infected. Four of the twenty rifle bullet wounds were clean, but the infections of the remaining sixteen were milder in nature than in the case of the shrapnel wounds. It was not at all surprising to find the shrapnel wounds infected, considering the amount of foreign material found in them. It was often possible to identify the red and blue material of the French soldiers' uniforms. Pieces of straw and wood were occasionally found.

The following table shows the nature of the injuries and the parts of the body affected, in order of frequency:—

Fracture of the radius.....	1
Wound of the nose.....	1
Fracture of the ulna.....	2
Traumatic amputation of the thigh.....	2
Fracture of a metatarsal bone.....	3
Fracture of the skull.....	3
Fracture of the pelvis.....	3

Fracture of the scapula.....	4
Fracture of a rib.....	4
Fracture of the jaw.....	4
Fracture of a phalanx.....	4
Wound of the knee-joint.....	4
Fracture of a metacarpal bone.....	4
Injuries to the spinal cord.....	5
Injuries to the eye.....	5
Penetrating wounds of the abdomen.....	5
Penetrating wounds of the thorax.....	6
Fracture of the tibia.....	8
Fracture of the fibula.....	8
Fracture of the femur.....	9
Fracture of the humerus.....	20
Flesh wounds.....	35

The point of chief interest in this table is the comparatively small number (5) of penetrating wounds of the abdomen. These five cases, I think, very fairly represent the small proportion of recoveries from these wounds. The vast majority of these cases must die on the field of battle or in the trenches.

There were four cases of infection with the *Bacillus aerogenes capsulatus*, of which three recovered, an amputation at the thigh being necessary in one of the cases. A great many of the wounds contained gas on admission to the hospital. The *Bacillus coli communis*, or some other gas-forming organism, was most often responsible.

The usual procedure was to take all cases, upon admission, to the operating room and give them an anaesthetic. Then the part of the body affected was shaved, if necessary, and cleaned with turpentine, soap and water, and bichloride. In infected cases, the wounds of entry and exit were enlarged, and all gross foreign material and unattached fragments of bone removed. The wound was then irrigated with peroxide of hydrogen. Suitable drainage was established, and a sterile dressing and splints, when necessary, were applied. The subsequent treatment consisted in daily dressings and irrigation.

The majority of the patients we received in Paris were French. During September a good many English were sent to Paris, but during October and November they were sent to base hospitals along the coast, and from there shipped back to England. Before I left in December, some of the English wounded were again being sent to Paris. There were a few Turks and Senegalese. The German wounded brought to Paris were sent to military hospitals, where they could be confined as prisoners.

Upon their arrival at the hospital the wounded were much exhausted. It was not uncommon to see them sleep the greater part of the first forty-eight hours. They appreciated, as I have never seen any one before, the luxury of a comfortable bed with its clean sheets, a hot meal, and last but by no means least, the cigarette offered them by their next-door neighbor. After recov-

ering from their exhaustion, they exhibited a resistance against infection, which spoke for a sound system and excellent physical condition.

The ambulance department of the hospital was a most important one. Starting with only a few cars, this has grown, until now there are upwards of seventy cars in the employ of the hospital. These cars are all driven by Americans, and are attached to different parts of the French and English lines. Their business is to carry wounded back from the field dressing stations and field hospitals, to base hospitals, which are usually situated near a rail head. Quick evacuation of the wounded back to permanent base hospitals has a greater effect on the reduction of mortality than any one other measure. The English found that the mortality was so great from shipping their wounded across the channel, that they were compelled to give it up. So the ambulance has come to play a most important part in the present war, as a connecting link between the trenches and the nearest rail head. When I left Paris early in December, we were receiving patients who had been wounded the day before, and in some cases even on the day of admission.

In summing up the treatment of wounds in the present war, it seems to me that a greater degree of conservatism has shown itself than ever before, except in the cases of compound infected fractures of the lower extremities. In these latter cases amputation is more early resorted to than formerly, with the idea of saving the individual many long years of chronic bone disease. Otherwise, the methods employed are a combating of the infection by means of ample drainage and antiseptic irrigations.

REPORT ON THE ALLEN TREATMENT OF DIABETES.

BY LEWIS W. HILL, M.D., BOSTON,

AND

JOSEPH L. SHERRICK, M.D., BOSTON.

[*West Medical Service, Massachusetts General Hospital, Dr. Richard C. Cabot, Boston, Chief of Service; Dr. William H. Smith, Dr. Roger I. Lee, Visiting Physicians.*]

DR. FREDERICK M. ALLEN of the Rockefeller Institute, New York, read a paper in Boston Dec. 2, 1914, before the Suffolk District Medical Society, on his new starvation treatment of diabetes, following the principles laid down in his monograph "Glycosuria and Diabetes." We were so much impressed by his paper that we decided, at the suggestion of Dr. Roger I. Lee, who was then in charge of the service, to try the treatment on a series of cases.

Previously to this our treatment of diabetes on the West Medical Service had been to start the patient off with a fairly high carbohydrate intake, about 100 grams; with 100 grams of protein and 250 grams of fat, or more, and gradually to work down from this, first cutting down the carbohydrate, and then, if the patient did not become sugar-free, cutting down the protein. The fat was always kept high and many patients received over 4,000 calories, our old idea being to make the patient gain weight if possible. If the patient lost weight we were afraid, and we feel that one of the most important things that Dr. Allen has brought out is that a diabetic can lose a good deal of weight with considerable advantage to himself and no harm. We also used "vegetable days" and "oatmeal days"—usually with rather poor results. As to starvation, we were afraid of it, although in one or two cases we had used a semi-starvation day, with thick cream and black coffee, but never for periods of longer than one day at a time. With this treatment our diabetics did fairly well, but the process of getting them sugar-free was a tedious one and a good many cases continued to excrete 0.1% or 0.2% of sugar no matter what we did.

We do not intend to discuss the theory of the Allen treatment—he did that in his original paper—but merely to report our very successful series of cases, in order to show that his treatment is simple, safe and very efficacious in rendering and keeping a patient sugar-free, in a much shorter time than was possible by the old method; that anybody can do it, and that there is no danger of coma.

Our method of treatment, following Dr. Allen's very closely, is as follows: As soon as the patient enters the ward he is put on house diet

without extra bread or potatoes and kept on this for two days to determine his tolerance for ordinary diet and the severity of his diabetes. On the third day he is put to bed and given nothing but black coffee with one ounce of whiskey every two hours from 7 A.M. to 7 P.M.—7 ounces of whiskey in all—representing about 800 calories. The whiskey is usually well borne, although in one or two of the female cases it had to be omitted as it caused nausea. If there is much acidosis, as indicated by the amount of diacetic acid and acetone in the urine, sodic bicarbonate is given, otherwise not.

The patient is kept on this regime until he is sugar-free; in most of our cases it took either two and a half or three days to accomplish this. The loss of weight is very slight; the relief of symptoms, such as pruritus, polydipsia, etc., is very striking and we have never seen any indication of acid poisoning in the cases we have treated by this method. On the whole, patients seem to bear starvation remarkably well. We have never starved a case longer than three days, but would not have hesitated to do so had there been any sugar in the urine at the end of this time.

As soon as the patient is sugar-free he is given a "vegetable day," i.e. vegetables containing not over 5% of carbohydrates, boiled twice, with a carbohydrate content of about 15 grams after boiling (in the boiling about half the carbohydrate is lost). After a single vegetable day the diet is changed to:

Carbohydrate 15 grams
Protein 25 grams
Fat 150 grams

(Our vegetable diets, as well as several other sample diets are given below). From this the diet is slowly raised, increasing first the fat, then the protein and lastly the carbohydrate. The fat is never raised above 200 grams and the calories seldom above 2,200. On this the patients hold their weight, feel well and usually remain sugar-free. They do not gain weight; but as Dr. Allen says, it is much better to be lean and healthy than to be fat and carry one or two per cent. of sugar. Indeed, in some of the more robust cases who are obese, it seems desirable to get rid of this and the calories are kept low on this account. This is supported by Dr. Allen's experiments with his de-pancreatized dogs, for he found that as soon as he tried to make these dogs grow fat they died, whereas if he fed them on only a small amount, and was content to let them stay very lean, they did very well.

Our series is small, and perhaps we have been lucky, but in no case have we had any unfortunate results—never any sign of coma. In every case the patient has become sugar-free and has stayed so, on a reasonable diet which enabled him to hold his weight.

Some of these were severe cases of diabetes,

young people, whom we had treated before by the old method and could not get sugar-free.

When the patient is discharged from the ward he is given written diet slips with two or three menus which he can use on different days, figured out carefully to correspond with his tolerance. The two most important things to remember in this treatment are the following:

First, do not raise the diet too quickly after starvation, and pay just as much attention to the protein intake as to the carbohydrate.

Second, do not worry if the patient loses weight; it will not hurt him.

CASE REPORTS.

The first three are cases which were treated first with the old method and could never be made sugar-free, running from 0.1% to 0.2% of sugar. On the new treatment they responded promptly and were discharged sugar-free.

CASE 1. A woman of 64, diabetic for two years. She was sent in from the out-patient department, where she had been receiving a diet of 50 grams of carbohydrate and 50 grams of protein. On this diet she was putting out 8 grams of sugar a day with moderately strong acetone and diacetic acid reactions in her urine. When the carbohydrate was cut, in the ward, to 30 grams she put out 3 grams of sugar a day. She complained of severe pruritus vulvae. After 16 days of this treatment she continued to put out from 0.1% to 0.2% of sugar a day. Allen's treatment was then started, and after one day of starvation she was sugar-free and remained so for four days on a diet of carbohydrate, 20 grams; protein, 30 grams; fat, 150 grams. The itching had gone. Then the protein was raised to 80 grams, with the carbohydrate at 20 grams, and she immediately showed 1.5% of sugar. This is very important; the protein should not be raised too quickly. This we did not realize in our earlier cases.

A second starvation day, followed by two vegetable days, and a more careful raising of the diet—as follows—kept her sugar-free, and she was discharged so. Her diets were:

Dec. 12. Carbohydrate, 20 grams.
Protein, 30 grams.
Fat, 150 grams—1500 calories. No glycosuria.

Dec. 15. Carbohydrate, 30 grams.
Protein, 30 grams.
Fat, 200 grams—2000 calories. No glycosuria.

Dec. 20. Carbohydrate, 30 grams.
Protein, 40 grams.
Fat, 180 grams—2000 calories. No glycosuria.

Dec. 26. Carbohydrate, 40 grams.
Protein, 40 grams.
Fat, 180 grams—2000 calories. No glycosuria.

Dec. 30. Carbohydrate, 50 grams.
Protein, 50 grams.
Fat, 180 grams—2000 calories. No glycosuria.

Weight on entrance, 119 pounds.

Weight at discharge, 116 pounds.

CASE 2. A Jew of 49, at entrance had 175 grams

of sugar (5.5%), acetone slight, diacetic acid absent. Treated for three weeks with the old method, he got down to a diet containing carbohydrate 15 grams, protein 50 grams—but still put out from 3 to 8 grams of sugar a day. By the old method we could not do away with the last traces of sugar.

The Allen treatment was started with two starvation days. On the second he was sugar-free—but showed 2.6 grams of sugar the following day on 12 grams of carbohydrate and 40 grams of protein. (This was one of the earlier cases when the diet was raised too quickly after starvation.) After one more starvation day and two vegetable days he stayed sugar-free while the diet was raised slowly to 30 grams of carbohydrate and 45 grams of protein, calories about 2000. Discharged sugar-free on this diet.

Weight at entrance, 109 pounds.

Weight at discharge, 110 pounds.

CASE 3. A man of 35, a severe diabetic, entered Dec. 28, 1914. He had been in the hospital the previous July for a month and could never be made sugar-free with the old method of treatment. At entrance he was putting out 2.5% of sugar (135 grams) per day with strongly positive acetone and diacetic acid tests. Two starvation days made him sugar-free, but we made the mistake of not using twice boiled vegetables for his vegetable day after starvation. So on this day he got about 30 grams of carbohydrates, and for a few days he showed from 0.2% to 1% of sugar. Another starvation day was given him and he became sugar-free. This time his vegetables were closely restricted and he was given only enough twice-boiled vegetables to provide about 15 grams of carbohydrates. After this the diet was raised very slowly. He remained sugar-free for three weeks and was discharged so on.

Carbohydrate, 30 grams.

Protein, 40 grams.

Fat, 200 grams.

At no time did he receive more than 2200 calories.

Weight at entrance, 139 pounds.

Weight at discharge, 138 pounds.

These three cases were the first ones we tried, and in each one of them we made the mistake of raising the diet too quickly—either allowing too many vegetables on the vegetable day, or raising the protein too quickly afterwards. With the later cases, after we had more experience, there was no more trouble.

CASE 4. A Greek (male) of 48, diabetic for two months, entered Jan. 14, 1915, with 3.8% (65 grams) of sugar and moderate acetone reaction. There was no diacetic reaction present at entrance. After one starvation day he became sugar-free, but was kept on starvation one day longer and then started on vegetables in the usual way. After the third day a moderate amount of diacetic acid appeared in the urine and continued. The ammonia rose from 0.7 grams per day to 2.6 grams per day, and then varied from 0.3 to 1.5 grams per day. No symptoms of acidosis.

Jan. 18. Carbohydrate, 15 grams.

Protein, 25 grams.

Fat, 150 grams—1360 calories. No glycosuria.

- Jan. 20. Carbohydrate, 15 grams.
Protein, 25 grams.
Fat, 200 grams—1571 calories. No glycosuria.
- Jan. 24. Carbohydrate, 25 grams.
Protein, 35 grams.
Fat, 200 grams—1760 calories. No glycosuria.
- Jan. 26. Carbohydrate, 35 grams.
Protein, 40 grams.
Fat, 200 grams—1838 calories. No glycosuria.
- Jan. 29. Carbohydrate, 45 grams.
Protein, 50 grams.
Fat, 200 grams—2194 calories. No glycosuria.
- Jan. 31. Carbohydrate, 50 grams.
Protein, 60 grams.
Fat, 200 grams—2347 calories. No glycosuria.

Discharged Feb. 1 sugar-free on this diet.

Weight at entrance, 160 pounds.

Weight at discharge, 156 pounds.

This was not a severe case and responded very easily to treatment.

CASE 5. A female of 59, a diabetic of two years' standing, excreted 2.6% of sugar on Jan. 16, 1915, with no acetone or diacetic acid reactions in the urine. Severe pruritus vulvae. Starved two days; sugar-free on the second starvation day, with disappearance of the pruritus.

- Jan. 21. Carbohydrate, 15 grams.
Protein, 25 grams.
Fat, 150 grams—1595 calories. No glycosuria.

From this time the diet was slowly raised until on Jan. 30 she was getting

Carbohydrate, 35 grams.

Protein, 45 grams.

Fat, 200 grams—2156 calories.

She was sugar-free on this and was discharged to the out-patient department after a two weeks' stay in the wards.

Weight at entrance, 135 pounds.

Weight at discharge, 133 pounds.

CASE 6. A man of 52, entered Jan. 10, 1915, with 1% of sugar. He entered for arteriosclerosis and hypertension and the sugar was found in the routine examination of the urine. He was kept on house diet for a few days and his sugar rose to 3.5%. No acetone or diacetic acid. After two days of starvation he became sugar-free and continued so as the diet was slowly raised. He was kept sugar-free in the ward eighteen days and was sugar-free on Feb. 6 with a diet of

Carbohydrate, 60 grams.

Protein, 60 grams.

Fat, 200 grams—2280 calories.

On Feb. 7 the protein was raised to 80 grams and 0.2% of sugar appeared in the urine. The proteid was then reduced to 60 grams and he remained sugar-free on this diet and was discharged so.

In this case after starvation a moderate amount of acetone appeared and continued. No symptoms of acidosis. The ammonia ran from 0.3 to 1.0 grams per day.

Weight at entrance, 160 pounds.

Weight after three weeks' treatment, 156.

Maximum caloric intake, 2525.

CASE 7. A young man of 25, diabetic for eight months, entered Jan. 20, 1915, with 6.6% (112 grams) of sugar and strongly positive tests for acetone and diacetic acid. After a period of two starvation days he was sugar-free and actually gained three pounds in the process of starvation (probably due to water retention).

His diet was then raised as follows:—

- Jan. 24. Carbohydrate, 15 grams.
Protein, 25 grams.
Fat, 150 grams. No glycosuria.
- Jan. 26. Carbohydrate, 20 grams.
Protein, 35 grams.
Fat, 175 grams. No glycosuria.
- Jan. 29. Carbohydrate, 20 grams.
Protein, 45 grams.
Fat, 200 grams. No glycosuria.
- Jan. 31. Carbohydrate, 30 grams.
Protein, 45 grams.
Fat, 200 grams. No glycosuria.

At entrance his ammonia was 1.7 grams per day; after the starvation days it ran from 0.9 grams to 0.3 grams per day. The acetone was a little stronger than at entrance; the diacetic absent except on three days.

On Feb. 5 he was still sugar-free (having been so since his starvation days two weeks previously, and weighed 127 pounds, a gain of seven pounds since entrance. At no time did he receive over 2150 calories.

This was a very satisfactory case; no doubt the carbohydrate could have been raised to 50 or 60 grams, but he was doing so well that we felt it unwise to go any further.

CASE 8. A young man of 20 entered Jan. 30, 1915, with 4.5% (75 grams) of sugar, acetone moderate, no diacetic acid. After two days of starvation he became sugar-free and continued so on two vegetable days. After this his diet was raised as follows.

- Feb. 3. Carbohydrate, 15 grams.
Protein, 25 grams.
Fat, 150 grams—1320 calories. No glycosuria.
- Feb. 8. Carbohydrate, 20 grams.
Protein, 35 grams.
Fat, 175 grams—1850 calories. No glycosuria.
- Feb. 14. 25 grams.
Protein, 50 grams.
Fat, 175 grams—1880 calories. No glycosuria.

It seemed wise to keep this case on a restricted diet for a considerable length of time, as he was a severe diabetic, and so we did not attempt to push up the carbohydrate. He is still in the wards, doing very well on this diet, sugar-free and holding his weight.

Weight at entrance, 116 pounds.

Weight Feb. 14, 115 pounds.

Ammonia at entrance was 1.3 grams per day. On the first starvation day it dropped to 0.3 grams, never rose above 0.7 grams, and on Feb. 14 it was 0.16 grams per day. Moderately strong acetone and diacetic acid reactions.

ACETONE, DIACETIC ACID AND AMMONIA.

Of course the great bugbear of any starvation treatment is coma. We have seen no coma nor any signs of it in the eight cases we have treated.

The ammonia has always been low, only in one case reading as high as 2.5 grams per day, which is not at all a high ammonia. Indeed, in most of the cases it has been very low, usually under a gram a day. This very possibly is due to the low protein intake.

We have seen nothing constant in the appearance or disappearance of the acetone and diacetic acid while on starvation. In one case both disappeared, in others they increased slightly and in others stayed practically the same. (Rough quantitative estimations only.)

WEIGHT.

It will be seen that in most of the cases there has been no striking change in the weight, and we feel that most diabetics while in the ward, at any rate, can get along very nicely on 2,000 calories. The patients are kept in bed only during the starvation; after this they are up and around the ward.

No patient has lost more than 5 pounds during his treatment (most of our cases were in the wards about a month) and no patient has gained more than 7 pounds. In most of the cases it will be seen that the weight at discharge was practically the same as at entrance. Of course the patients were not doing any vigorous work or exercise, and it is quite possible that outside the hospital they would not be able to get along on a diet of such a low caloric value.

Now it is one thing to treat a diabetic in a hospital ward where the diets, urine, etc., can be accurately controlled, and quite another thing to treat him at home. All our diabetics have been discharged to the out-patient department, and it has been found that practically all of them, no matter how well they may do on the ward, show sugar on their return to the out-patient department, perhaps a week or two after they have left the ward. For this reason we have had some very careful diets figured out (for which we are indebted to Miss Eckman, the dietitian of the hospital) and with these diets the patients can keep on just exactly the same food that they had while in the hospital. The time has been too short for us to follow many of these cases on the outside, but we feel that most of them, who are of the average intelligence and perseverance, will do well.

Tea and coffee with saccharin is allowed with all these diets.

The bacon and pork is weighed uncooked, and in the calculation of fat and calories, allowance is made for the fat lost in cooking.

The calories in these diets are usually put in round numbers; a variation of 6 or 8 calories, one way or another, makes no difference.

LABYRINTHITIS FOLLOWING OPERATION FOR ATRESIA.

BY GORDON BERRY, M.D., WORCESTER, MASS.

THIS paper considers a case of atresia of the external auditory meatus with unfortunate complications following operation which has puzzled not only the writer but those with whom he has discussed the case. Let me sketch it out roughly that you may see at a glance the picture in its entirety.

HISTORY AND COURSE.

An apparently normal boy of fifteen years, Joseph D. by name, came to the hospital clinic complaining of deafness on the left. He gave a history of a mastoid operation on this side when a baby, and a brief record of the operation was found, but the writer was unable to discover either then or later any present trace of it, so complete was the healing. Examination revealed a normal ear on the right and a normal auricle on the left, with the left auditory canal entering only as far as the bony isthmus, where it became occluded by a solid bony wall. Hearing tests revealed a functioning cochlea. He had been advised by men at the New York Eye and Ear Infirmary (patient's statement) to have an operation performed on this ear. The fact that the canal was already patent two-thirds of the way, making an operation seem relatively simple, was probably instrumental in persuading them to this conclusion, as it did three of us who saw the case in Worcester. The operation was performed in December, 1913, or thirteen months ago. The technic consisted in continuing the canal opening by chisel and curette, somewhat after the method of the Heath operation, until a tympanum was reached. This was carefully left alone. After five days the artificial canal was skin-grafted, not the middle-ear. The hearing was improved. Granulation tissue began to spring up actively in the middle ear, though the operator had thought himself successful in not injuring this cavity. After two weeks a very slight irregularity of gait (toward the left) was noted but not given any significance. In three weeks the boy walked home from the hospital and, on the way, first showed any marked labyrinthine symptoms by falling. Vertigo became rapidly worse. An ocular nystagmus was present and was such as a labyrinthitis on the operated side would give. Clear negative spinal fluid under pressure was removed, without relief. The boy gradually became unruly, irrational, and at times very noisy. He could not stand alone without falling (to the left). His speech was thick and slurred, like that of a drunken man. After waiting two months from the first operation, it was decided that the vertigo would not disappear without

help, and on the basis that it was caused by granulation tissue pressing on the oval and round windows, a radical mastoid exenteration was performed and the offending tissue in the tympanic cavity removed as thoroughly as possible. A primary skin-graft was applied to further control granulations. For a month he was better, but not much. The granulations required repeated cautery and instrumentation to keep under control. At the dressings, pressure applied to the middle ear region made the symptoms of vertigo and muscular incoördination worse. Consultation with surgeons and neurologists offered no solution excepting the suggestion that any measure offering possible relief was justifiable. Meningitis and brain-abscess were considered, only to be ruled out. Two months and a half were allowed to pass, and conditions, instead of improving, were becoming aggravated. The cochlea and the labyrinth on the operative side both responded positively to tests and were consequently active. The mastoid was at no time tender, nor did he complain particularly of headaches. Concluding that granulations had worked their way through the oval or round window and in some way were proving a source of irritation, it was decided to destroy the labyrinth and part of the cochlea in so far as possible on that side, with the expectation that the other side would soon offer compensation and matters clear. Desiring to make this a final effort, the writer did not satisfy himself with tapping the external semi-circular canal or with entering the promontory. Each canal was opened for over half of its circumference. The vestibule was entered from behind and from in front, and easy access established for a probe to pass under and around the facial canal (without disturbing the nerve). The bridge between the oval and round windows was broken down and the basal whorl of the cochlea exposed from here forward until it disappeared around the bend. A slight cerebrospinal fluid escape was noted on opening the horizontal semi-circular canal.

Operative Anatomical Findings. 2.5 cm. in from the anti-tragus or 1.2 cm. from the cochlea (the right drum-head was 3.1 cm. from the anti-tragus), a large canal closed itself off in a smooth-walled round cavity. For a little way there seemed to be a fissure-like lead toward the tympanic cavity, but this became rapidly obliterated. 2-3 mm. further in an opening was found which soon emptied into a typical tympanic cavity, of about the normal size. No drum was present. A suggestion of tympanic ring was seen. No ossicles were found. The middle ear appeared to be lined with thin mucous membrane, and the first operation was stopped here in the hope that this membrane would help to keep the cavity open. The radical and labyrinthine operations revealed still no ossicles, a patent eustachian tube, apparently an open oval window, a small attic, a small antrum, somewhat undeveloped mastoid cells, small pneumatic in type, normally placed semi-circular canals and vestibule and cochlea and facial canal, a vestibule of the usual size, no tensor tympani as far as could be seen. It should be noted that the search for the stapes was made in a mass of fibrous granulation tissue and it may well have escaped detection. Most writers report the presence of this ossicle.

POST-OPERATIVE COURSE.

The labyrinth operation was performed on April 30, 1914, four and a half months after the first

operation. The irritative symptoms referable to the affected side and present before the labyrinthectomy, were now almost gone, and a more marked nystagmus referable to the sound side developed. Following the operation there was a short period of constantly rational mentality. The temperature, which had been normal, rose to 100 or 101° in the afternoon for two weeks, and then quieted. There was an abundant serous flow on the dressings. After three weeks he was gotten out of bed to walk a few steps each day. Granulations were encouraged that the connection through to the meninges might become blocked off. This occurred one month after the operation, and was followed that night by vomiting and paralysis of the external rectus on the operated side. The pupillary reflexes remained normal; photophobia was present and remained for several weeks. The white count at this time was low as usual (7,400). The withdrawal of clear negative spinal fluid from time to time alleviated symptoms a little. Vomiting two to five times daily continued for two weeks, with partial suppression of urine. Caloric and turning tests showed the labyrinth on the operated side to be destroyed, but the hearing apparently but little changed by the opening of the cochlea. In the middle of June, one month and a half after the labyrinth operation, a much reduced cavity was scabbed over, dry, and all but healed, this scab being removed a week later to reveal a completely epidermatized cavity.

Extracts from bed-side notes:—

January. 7th. Ocular nystagmus to right and falls to left. 12th. Cold syringing to A. S. increases right nystagmus; cold syringing to A. D. stops a little the right nystagmus and gives left nystagmus. Blood pressure, 120 mm. 18th. Right turning, head 30° forward; after nystagmus, left, 40-50 seconds; left turning, after nystagmus, right, 50-60 seconds. 15th. 30 c.c. spinal fluid out under pressure, causing frontal headache for five minutes. 21st. 3-4 drops only of spinal fluid out. Noisy. Shurs words more.

February. 4th. Quiet if in bed. Noisy when up in chair. Right nystagmus same; only slight nystagmus to left. 12th. Worse. More noisy. Hid under bed to escape a sick child in next bed which he claimed was annoying him. Radical mastoid operation. 15th. Quieter. Speech a little more slurred. Nystagmus better. 18th. Mentally more rational for first time since radical operation. Speech and nystagmus a little better. 19th. Out of bed for a few steps. 23rd. Walks alone but with difficulty.

March. 8th. Tried his hearing for piano music. Objected to playing the upper notes; enjoyed music in the middle register; did not mind playing in the lower register. 12th. Fell out of his wheel chair. More dizzy. Been unable to walk alone for two weeks. 15th. Hard to manage in the ward. Disobedient. 19th. Nystagmus to either side. Cold syringing for one-half minute in either ear (head back 60°) aggravates this; and this induced nystagmus better on sitting up, to return on lying down. 30th. Limbs seem more incoördinated in left hand and right foot.

April. 7th. Pressure with probe in middle-ear region always exaggerates the vertigo and incoördination. 28th. Cold syringing left, gives nystagmus. Right in 1 1/2 minutes, lasting 3 1/2 minutes. Cold syringing, right, gives nystagmus, left in 1 3/4 minutes, lasting 4 1/2 minutes. 30th. Labyrinth operation.

May. 2nd. Voluntary nystagmus to right marked.

Controlled on looking to extreme left. 5th. No change excepting less control over left arm. 13th. More irritable. Got out of bed and tore off bandage. 15th. Note a slight nystagmus on looking to left. Voluntary nystagmus to right continues. 19th. Restive and disobedient. Pulled off dressing. 22nd. Out of bed a little. 25th. Seems stronger. Walked twice the length of the ward with help. Almost no meningeal discharge from cavity.

June. 2nd. No serous discharge from cavity today. Vomited twice last night. Partial paralysis of right external rectus. 3rd. 30 c.c. spinal fluid out under slight pressure. Left limbs are more spastic and jerky. Partial urine suppression. 5th. A little quieter but vomited twice last night. 11th. Averages two vomitings daily, and urinating once a day. 15th. Vomiting worse; five times today. Ear cavity shows dry scab. 18th. Patient finds that rotating his own head makes him vomit and temporarily relieves his nausea and the bad taste in his mouth. Vomited but once today. A mouth wash helps. 21st. Urine more free. Up on feet today, showing a little better control. Ear cavity epidermatized.

July. 1st. More steady on feet. 5th. Photophobia. Crawls around when nurses are not watching (not trusting his legs). Nystagmus more marked. 11th. Photophobia gone. 15th. Nystagmus less. 23rd. Cold syringing to A. S. gives no reaction in six minutes; to A. D. gives nystagmus in 1 1/4 minutes, gone in 2 1/2 minutes.

By two months after the labyrinthine operation the external rectus paralysis had become much less, and has since remained almost the same. The vomiting stopped; the slurred speech became a little better. The ear continued healed. Late in September (or five months after the last operation) there was but little further change. Under the conviction that there was some deeper-seated irritative or pressure focus at or near the floor of the brain, causing the ocular muscle paralysis, the ataxia, and the vertigo, and feeling that this came under the province of the brain-surgeon, I sent Dr. Harvey Cushing a brief account of the case, in the hope that he might shed some light upon the matter. He most kindly consented to do what he could, and added that my history suggested a serous meningitis, for which he feared but little could be done. We were preparing to send the patient to the Peter Bent Brigham Hospital, but at just about this time he began to improve and we kept him in Worcester. He was increasingly able to control his limbs and unruly periods were less frequent; and he could speak more distinctly.

One year after the first operation and seven and a half months after the labyrinthectomy, he was finally discharged from the hospital. At this time he could walk the length of the ward unaided, but with a characteristically halting gait, could walk up and down stairs, could feed himself, could read, and could speak clearly. He went home to trying conditions, where nagging children, a drunken father, and an over-worked mother made life unpleasant. The boy became steadily worse until in a fit of temper last week he began throwing furniture about the room, and broke a window with his bare hand. The ambulance took him to the police station and thence back to the hospital, where he is now, without since having any further outbreak. During this stay at his home last month he was taken to the State Insane Hospital near the city,

and for a week subjected to careful tests with a view to possible admission; after which he was returned home and declared not insane nor more mentally deficient than his up-bringing could account for.

CONSIDERATION OF CASE.

The case divides itself naturally into two heads: that dealing with the atresia, and that dealing with the labyrinthitis. First as to the atresia and its operative remedy,—Bezold has estimated that one out of two thousand cases show unilateral or bilateral microtia and atresia. The operation has been performed a good many times here in Boston with varying degrees of success. In most cases it has been done in children where both ears were involved. Against the argument that an external deformity infers internal impairment, rendering operative interference useless, Politzer and Kerrison point out that the middle and internal ear come from different embryonic sources than the external; and that faulty development of the latter by no means infers variations in the former. Alexander¹ deduced from many autopsies that in the vast majority of cases with congenital deformity of the auditory tract, the deformity was limited to the conducting apparatus alone, or to the perceiving apparatus alone. Looking at it from the other side, Page² says that "it can be definitely stated that cases of defective development of the internal ear are rarely if ever found to be associated with atresia of the canals in otherwise healthy infants." For instance, one never sees a microtia in a deaf-mute. Alexander¹ insists on a patent eustachian tube, and no facial paralysis, as evidence of normal development of the middle and internal ears. When the child is old enough, the activity of the cochlea can be demonstrated by a hearing test, as was done in the case before us.

Hearing Tests. In this case despite the partial destruction of the cochlea, we seem to get a better hearing than was present before. The sound right ear was almost normal and need not be considered here. On the left, the low whisper vowel sound ("four") could not be heard before the operation; now he hears it at four to five inches away, and the low consonant sound ("six") at fourteen feet (a high note). The loud whisper was heard "ad oram," now he hears it at sixteen feet. The bone conduction has remained the same, seven seconds for a 512 vs. fork (normal = 12"). The bone conduction on the right was also seven seconds. He hears all the forks by bone, and in the left ear when applied to the mastoid, excepting the 64 vs. fork. By air he fails to hear the lower forks, the low limit before the operation being 2048 vs., and after the operation, 1024 vs. From there up he hears the remainder of the normal tone scale excepting possibly a little shading off of the top register. Barany's noise-apparatus was not employed until after the operation on the labyrinth, and appears to negative the contention that the hearing was maintained or distinctly improved, as with its use in the sound ear, he can only distinguish a shout on the left. The writer is inclined to question the absolute value of this test in this case, as the sound ear was plugged

very tight during the repeated whisper tests, ointment being used to further ensure a complete closure of all possible crevices around the plug.

Page's² cases show the development of a working hearing in most of them. Kosokabe³ reports two cases operated on by him in Japan and benefited. Danziger⁴ of New York gives a successful case of particular interest here, as it was the only one the writer could find reported as developing post-operative labyrinthine symptoms (in a nystagmus to the affected side). But this came on four months after the operation, when the patient had been discharged healed, and is ascribed to an erysipelas which developed at this time: the labyrinthitis being due to a "collateral edema". Lewin⁵ of St. Petersburg, also reports a good result. The literature is surprisingly scanty when one considers the number of cases which must go to operation.

This leads to the question of the operative method to be employed. Because the jaw articulation was usually so far back in these cases, Michael Jaeger^{2,6} suggested in 1837 that the entrance be by way of the mastoid cells and antrum. Using this suggestion, some have made this the avenue of approach and skin-grafted up into the antrum, but not with good results. The more recent workers, realizing that the stapes alone is likely to be present, and appreciating the extreme difficulty of keeping the granulations down through a small canal, do not try to preserve the middle ear but recommend a radical tympano-mastoid exenteration, and an early skin-graft. This affords room to work in and moreover ensures a canal which later cicatricial contraction will not make too small. Dr. Page² expresses well the more advanced conservative opinion when he concludes: "that operation is warranted in practically every case of congenital bilateral microtia with total osseous atresia which occurs in an otherwise well-formed infant; that when the child has reached the age of two years and his attention can be attracted by sounds through the air, such as whistles, calls, etc., x-ray photographs should be made (under anesthesia), and the operation should be performed through the mastoid, posterior to the line of the canal. The antrum should be opened and, unless a normal drum-membrane be found, the contents of the tympanum with the exception of the stapes should be entirely removed and a large exposure of the inner tympanic wall obtained. Injury to the jaw can be avoided by working from the antrum forward. The eustachian tube, if present should be closed by curetting."

To go more into detail with regard to the labyrinthine complication following the operation, in an effort to determine whether the results in this case should condemn operating on atresia, necessitates taking up the mental aspect of this case. The boy had not been noted as being particularly backward in school. During

the routine ear examination prior to the first operation he seemed to the writer to possess the average amount of intelligence of a boy of the street. He certainly was normal gaited and spoke distinctly and to the point. Subsequent examination by neurologists pronounced him a mental deficient. Further, an examiner from the Waverley School for Defectives tested him and reported his mental capacity to be that of a boy of ten. It was pointed out that the lad had begun life as an illegitimate child; that a habit of self-abuse established over a year prior to his coming under our observation would indicate moral obtuseness; and that further evidence of mental deficiency could be gained from his disposition when at his best, to hector the older patients or tease the children; or at his worst, to do them physical violence, tear off his own dressing, yell at the top of his voice when angry, or refuse to do as bidden by the nurses. Over against this is the evidence as presented by the asylum authorities that the boy is neither insane nor mentally deficient. The writer is inclined to the opinion that he is a little deficient or backward, if you will, but accounts for these paroxysmic outbursts as merely evidences of an uncontrolled temper which could be generally traced to some irritative cause.

But this explanation does not bring us to a solution of the post-operative complications. We have here a clean initial operation, relatively simple, keeping relatively clean. At a time when the granulation tissue had begun to develop more rapidly, we first get a labyrinthine irritation. A low white count, the absence of temperature, a normal pulse, a negative fundus examination, a negative Wassermann reaction, negative spinal fluid (negative to the globulin reaction, reducing Fehling's solution, sterile, and with normal specific gravity and cell count): these all tend to combat the meningitis idea. From here on the tale is a pure repetition in which we are trying to catch up with Trouble.

Having thus considered the subject of atresia, operative methods for its correction, and the untoward results which this particular case developed, permit me to enter for a moment the other phase into which this discussion naturally leads us, that of the labyrinthitis. In our case there was a certain amount of sepsis in spite of every precaution, and we must think of a possible infective labyrinthitis. But Rutin says in his report of fifty labyrinthine cases (p. 59) that an "acute otitis practically never gives rise to a circumscribed or a diffuse serous secondary labyrinthitis and only exceptionally to a purulent labyrinthitis." He calls attention (p. 42) to a rather frequent complication following the radical mastoid operation where we get a diffuse secondary serous labyrinthitis in one to three days, and clearing after three to five days.

There have been a good many labyrinthine operations done for severe vertigo or unbearable

tinnitus alone. For these the interference has become lately less radical till the writers satisfy themselves with tapping the horizontal canal, or they refrain from the operation altogether.

Labyrinthine Tests in This Case. 10. A reference to the labyrinthine reactions in our case may well be entered here. Before the labyrinthectomy, the tests showed a functioning labyrinth. The nystagmus was toward the right or healthy side. Rotation ten times gave an after-nystagmus toward the left of 40-50 seconds; and rotation to the left gave an after-nystagmus of 50-60 seconds to the right, giving a slightly longer reaction for the sound ear. At the time of reporting, there is a partial compensation so the proportions are not as extreme as they were at first, but we get an after-nystagmus of 12 seconds for the right turning, and of 30 seconds for the left turning.

If now the head be bent forward and the face toward the left shoulder, right turning stimulates the left superior canal, which is now horizontally placed, and gives an after-nystagmus of 12 seconds, while rotation in the opposite direction stimulates the right posterior canal and we get an after-nystagmus of 25 seconds. With the head forward, but toward the right shoulder, turning to the left stimulates the left posterior canal with an after-nystagmus of 11 seconds, while rotation to the right stimulates the right superior canal and we have an after-nystagmus of 25 seconds. In other words, the after-nystagmus referable to the right or sound side is twice as long as that referable to the left, in each instance; a result we would expect after the destruction of the left labyrinth.

The caloric reactions corroborate these results: Cold syringing to the affected ear before the labyrinthine operation elicited a nystagmus in 20 seconds, which disappeared in 4 1/2 minutes; and to the sound ear, in 1 1/2 minutes, which disappeared in 3 1/2 minutes. After the operation, cold syringing to the affected ear gave no response, even after six minutes of syringing, while the sound side gave naturally about the same reaction.

As to the voluntary nystagmus, before the operation it was marked to the sound side and slightly present to the diseased side (an irritative nystagmus), while immediately after the operation the nystagmus was entirely toward the sound side.

Falling is toward the left or in the direction of the slow component. In locating objects with his leg or hand, that is, using the localizing test, he tended to go to the left of the object sought. At present he still has more trouble in controlling the movements of his left arm. If anything, he points a little more to the left or to the outside with the left arm and normally with the right. After syringing the sound (right) ear with cold water, the right arm points to the right, while the left arm points uncertainly to either left or right, but seems less affected by the syringing than the right arm.

Probably on account of his ocular paralysis more than from the nystagmus, there is a tendency to keep the head about twenty degrees toward the left from the mid-line. When the nystagmus to the right was severe, he preferred to lie on his right or on the sound ear.

In other words, all the tests showed an initial labyrinthine or cerebellar irritation on the left, followed after the operation by an excessive irritative nystagmus, right, non-compensated, which later be-

came gradually compensated. Ruttin' says in this connection, that if the labyrinth was totally destroyed, compensation will ultimately become complete.

The tests above noted seem to show a total destruction of the affected labyrinth by the last operation. The vertigo was made worse as was expected, but why did not this clear more rapidly? Alexander¹ keeps his post-operative cases in bed six weeks and Ruttin⁷ deems ten days sufficient. This case has been months rather than weeks, and he cannot yet walk without noticeable attempts being made at muscular co-ordination. Must not the irritative focus be referred to the nerve path behind the labyrinth, or to the meninges? The future conduct of the case will be an effort to keep the boy under favorable conditions where he can continue to learn the control of his muscles. Judging from the past, the writer ventures to predict that ultimately the co-ordination will be almost perfect.

TO CONCLUDE BRIEFLY.

We have here a boy of fifteen operated on for a partial atresia with apparent improvement in hearing. Three weeks later and coincident with the springing up of troublesome granulation tissue in the tympanic cavity, a vertigo developed, which has persisted in spite of a radical exenteration, and then a labyrinthine operation. Five weeks following this last operation, the closing off of the drainage from the meninges in the process of healing was attended by marked symptoms of meningeal pressure, which gradually subsided. The ear cavity became epidermatized in six weeks. Now, thirteen months after the first operation, the ocular nystagmus has become fairly well compensated, the hearing is apparently improved, but a muscular inco-ordination, though much better, continues. The consideration of the case naturally divides itself into two main headings, atresia and labyrinthitis, and is discussed above in the following suggestive phases: the age and operative method for relief of atresia; the results to be expected; the cause of the vertigo in this case; the time and the method for operating for labyrinthine vertigo.

LATER NOTE.

In the discussion following this paper Dr. Hurley offered the diagnosis of "Cyst of the cerebello-pontine angle." In the light of this suggestion the author has read Barany's original article on his Symptom Complex¹² as well as taken up again the tests with reference to their bearing on this explanation. He finds that such a retention of fluid as described by Barany would account for many of the symptoms: as certain phases of the nystagmus, and the pointing tests (see above); and the worse paroxysms seemed to be more or less periodic. On the other hand Barany's picture is not present here in its

entirety. For instance, there was but rare headache, and no pain or tenderness over the mastoid-emissary foramen; a complete stopping of the nystagmus to the left immediately followed the labyrinth operation; Barany's reported cases did not show a paralysis of the sixth nerve (though such might be expected); the hearing did not appear worse; and the lumbar puncture gave only questionable relief. Barany accounts for the cystic retention of the cerebrospinal fluid by inflammatory meningeal adhesions or some analogous agent. For such, in this case we could go back to the mastoiditis of infancy or find some anatomic abnormality, either of which would seem to be possible. The invariable aggravation of symptoms by pressure on the granulations in the tympanic cavity does not seem to be so easily explained, though the endolymphatic or nerve connection might account for this.

In short, Barany's symptom-complex, though not appearing to fit all the complications, does seem to explain many, and the writer would express his appreciation to Dr. Hurley for pointing out this possible solution, which the writer so gropingly anticipated when writing Dr. Cushing.

THE DIAGNOSIS AND TREATMENT OF SOME RARE FRACTURES.*

By WM. PEARCE COUES, M.D., BOSTON.

THE consideration and study of rare cases of fracture has a fascination all its own, especially as such study may help others when they encounter them. The knowledge obtained by the diagnosis of one of these rare types of fracture often leads to the recognition of others. Some of the types to be recorded are so unusual that the modern fracture text-books make no specific mention of them, others giving only a most cursory account, a few lines at most. In the general surgical text-books of modern date, some are not mentioned at all. The present question of industrial accident work, which is such a live one, will, I hope, add interest to the subject, as

*Read before the Somerville Medical Society, Feb. 4, 1915.

a recognition of unusual types of fracture becomes more and more important, on account of this new medical legislation.

The question of nerve lesion on account of fracture, except in certain classic fractures, is an almost unexplored territory. Undoubtedly, many obscure troubles from peripheral nerve injury on account of pressure from unrecognized fractures, remain undiagnosed.

The question of x-ray diagnosis of fracture is at the present time more important than ever. It is now an undisputed fact that certain fractures can positively be diagnosed only by the x-ray. This has been unfortunate in a way, as it has tended to make a careful clinical study of fractures suffer. "Let's have a picture," is too often heard in our hospitals and dispensaries, before a careful and painstaking examination is made. Cotton has well said that it is often best to have a radiograph after the diagnosis has been made, and correction of deformity attempted, instead of before. Particularly is this true in practice, where the patient has, perhaps, means to pay for only one visit to the radiographer. Most fractures can be diagnosed without the x-ray by careful patient examination. In children a few types, to be spoken of later, are impossible to diagnose, even under anesthesia. Of late we have heard considerable concerning the condition known as sprain fracture, especially from Ross¹ and Stewart of Philadelphia. The term, I think, is a bad one, as it is somewhat ambiguous. What is meant is that the so-called sprain or traction on ligamentous and tendinous structures produces fracture, often unrecognized, in many cases. If so, the case should be called a straight fracture—the sprain or force applied to the ligamentous structures producing the solution in the continuity of bone being a secondary matter. This condition has been called "masked fracture." Eisendrath spoke of it as follows, "The recognition of sprained fractures requires the systematic use of the x-ray in every case of severe sprain." Ross and Stewart estimated that 15% of the fractures treated in the German Hospital in Philadelphia in 1910 were so-called sprain-fractures. They considered that the x-ray was not essential to the diagnosis, and that the external malleolus was the most frequent site of the fracture. Fifteen per cent. of all fractures are sprain-fractures, according to Ross and Stewart. They believe that sprain-fractures probably are a part of the pathology of every dislocation.

A study of unusual fractures would be incomplete without reference to epiphyseal separations, some of the rarer forms of which were entirely unknown until Poland's classic work on the subject some 16 years ago.

We now pass to a consideration of some special types of fracture of rare or infrequent occurrence. They are of interest to all. They may be the next case we encounter in our work. I shall consider:

In the Upper Extremity:

1. Fracture of the trochlea of the humerus.
2. Children's Colles fracture (sub-periosteal fracture of the lower end of the radius).
3. Separation of the epiphysis of the first metacarpal bone.

4. Fracture of the carpal cuneiform bone.

In the Lower Extremity

1. Fracture of the fifth metatarsal bone by inversion of the foot, and the occurrence of the Vesalianum or bone of Vesalius in the foot, with its relation to mistaken diagnosis of fracture of the 5th metatarsal.

2. Separation of the lower epiphysis of the fibula.

3. Fracture of the middle and external tarsal cuneiform.

I shall dwell at some length on the first case, as it is very rare and the only correct treatment is operative.

Isolated fracture of the trochlea, the horizontal dice-box at the lower end of the humerus, is of very rare occurrence. Most of the cases are examples of bony injuries to the elbow, where this fracture has formed a part of more extensive injuries. Viewing the humerus laterally, we find at the lower end two half-moon shaped projections extending out at right angles from the shaft, the capitellum on the radial side, and the lip of the inner cone of the trochlea on the ulna. These thin, half-moon shaped projections are guarded on each side by the condyles; probably vulnerable only to force applied antero-posteriorly to the flexed elbow, except in cases of violent crushing injury, where the whole region is converted into a bag of bones. Operative intervention has been usually employed in isolated fracture of the capitellum, as the blocking of the joint usually persists till the fragment has been removed, *i.e.* it acts as a foreign body in the joint. The indications for operation in isolated fracture of the trochlea do not seem to be clearly laid down anywhere. Bony blocking can occur in exactly the same manner as with fracture of the capitellum.

REPORT OF CASE.

E. B., 12 years of age, was seen at the Surgical Clinic of the Boston Dispensary, Nov. 29, 1913.

Examination. Well-developed and nourished girl, no previous traumatism to the left elbow. Two weeks ago she fell on her left arm. She was told by a physician that she had torn a tendon in the wrist. She fell with her arm in front of her, striking the elbow on the sidewalk. The elbow was flexed, but how the force was applied to produce the fracture, she does not know. Physical examination showed very slight swelling and ecchymosis noted over the lower third of the ulna, flexor surface. There was slight tenderness on pressure here. The elbow was held semi-flexed. Active flexion or extension was impossible. The head of the radius rotated. Only a very few degrees of passive extension were possible. About the same amount with flexion. There was slight swelling in the region of the external condyle, with pain on pressure here, but

there was no crepitus. The radiograph showed in the lateral view a fragment of bone extending outward at an angle from the joint, upward. It was thought at first that this fragment was from the capitellum and that it was blocking the joint. The antero-posterior view showed nothing abnormal. Forced hyper-extension with pressure over the capitellum and then flexion, gave motion to an acute angle of flexion. It seemed as if manipulation had changed the position of the fragment slightly. The arm was put up in acute flexion. Other radiographs (lateral views) showed that the fragment seemed pushed slightly higher up. The arm was kept in the acute flexed position. Attempts to gain motion were unsuccessful. The elbow remained blocked as before. Nothing being gained after some weeks, operation was done on Dec. 26, 1913, under ether. Lateral incision on the radial side of the joint was made, dissection carried through the superficial and deep fascia and the joint opened. The region of the external condyle was explored and the capitellum exposed. It was found to be intact. Dissection and separation of tissues carried across the middle of elbow joint without finding fragment. I thought best,—unwisely, as it proved,—not to search longer for the fragment, as I supposed that, if the fragment was not the capitellum, recovery with a useful elbow would probably take place in time. Uneventful recovery to exactly the same condition as before operation. A long period was given for chance of improvement with massage and passive motion, but no substantial gain was made, and in August the joint was opened on the other side by Dr. Tenney, and the fragment successfully removed. Also uneventful recovery from the operation. The physical examination in November, 1914, showed extension to practically normal limits. Flexion about two-thirds—a considerable gain. No atrophy, slight keloid condition of the scar of the second operation. Radiograph at this time showed slight roughening where the bone was removed from about the lower end of the humerus.

A search of the literature of fractures brought to light only two other similar cases, which it is of interest to report very briefly with this one.

Fragment not visible.

Fig. 4.

Isolated Fracture of Trochlea.

X-ray tracing Dec. 4, 1913. Lateral view. Fragment plainly seen.

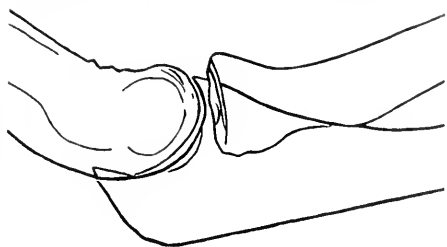

Fig. 5.

Isolated Fracture of Trochlea.

X-ray tracing Nov. 28, 1914. Lateral view after removal of fragment. Note slight roughening lower end of humerus.

They were found in Wendt's "Radiographic Studies of Fracture of the Lower End of the Humerus."

CASE 1. The first was a miner 27 years of age. Accident, Apr., 1908. He fell while working directly on the flexed elbow. Swelling of the left elbow and tenderness on pressure were noted. Flexion of 90 degrees, extension much limited, the radiograph in the antero-posterior view showed no bony injury to the elbow joint. In the lateral view, it showed on the flexor side of the joint a half-moon shaped shadow which was, exactly as in my case, thought to be capitellum. But a stereoscopic picture showed that it was from the middle of the trochlear surface of the humerus. Conservative measures gave no improvement in the position, so operative intervention was decided upon. The fragment was removed by open operation. Perfect healing. After operation and massage, flexion and extension were only slightly hindered. There was some grating in the joint; there was no muscle atrophy. In one year there was full return to normal in every way.

CASE 2. A miner, 28 years. History of direct fall on the flexed elbow. Examination showed right elbow much swollen, painful to pressure over the trochlea. Flexion to a right angle not possible. Extension of elbow much limited. Fluid in the joint. No abnormal mobility found. The x-ray picture in the antero-posterior view showed nothing but a minute-sized fragment in the distal border of the trochlea. The lateral view showed a half-moon shaped shadow from the trochlea. This was a direct hindrance to flexion. Stereoscopic picture showed that the shadow represented the forward, inner part of the trochlea broken off. Open operation was made, incision on the inner side of joint;

removal of the fractured piece; good recovery; at discharge, examination showed flexion and extension somewhat restricted; some grating in the joint; good scar; muscles not noticeably atrophied.

MECHANISM OF THE PRODUCTION OF THIS FRACTURE.

The rarity of the fracture, typical x-ray picture, the half-moon shaped piece of bone sticking up from the lower end of the humerus, only visible in the lateral view, make it of great interest. It would seem as if there must be a definite and constant method in the application of force which produces it. Unquestionably the production of this fracture is made by force applied to the flexed elbow, for it is a flexion fracture par excellence. My attempts to reproduce the fracture on the cadaver were unsuccessful. A direct blow on the upper part of the ulna, with the elbow flexed, gave a high fracture of the ulna. A direct blow on the lower end of the humerus over the trochlea, gave a clean separation of the whole of the lower humeral epiphysis. The only method which produced a fracture in any way similar to the clinical one was direct force, by mallet and forceps used as a chisel to the trochlea itself.

CHILDREN'S COLLES FRACTURE.

This fracture has never before to my knowledge been described with the above title. It is a sub-periosteal transverse fracture of the lower end of the radius occurring in children after a fall on the hand or lower end of the radius, in the same manner as the adult Colles fracture is received. The fracture is somewhat higher than the typical adult fracture. I have never seen a typical example in an adult, and I have seen about a dozen cases in all. The age most common is from 10 to 14 years. The fracture being sub-periosteal, there are clinically no deformity and no crepitus. The cases are often mistaken for sprained wrists. Locally, we have extreme pain on pressure over the seat of the fracture, very rarely ecchymosis and surprisingly little swelling. It is absolutely necessary to have two views, as in all fractures, when the radiographs are taken. The antero-posterior view may only show a little bulge on each side of the radius, low down, so slight as to be missed if one is not expert in interpreting radiographs of fractures. The treatment is not different from that of any other such fracture, without displacement. Recognition is the important thing, as unrecognized, the fracture may lead to subsequent trouble.

The following case illustrates this type of fracture:

CASE 3. K. M., 14 years of age, was seen at the Surgical Clinic of the Boston Dispensary, Dec. 26, 1914.

History. Four days ago she fell, striking on her left wrist. Exact position of arm and wrist when she fell not known to the patient.

Physical Examination showed very slight swelling

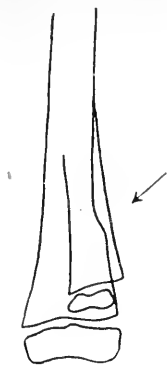

FIG. 1.

Children's Colles' Fracture.

X-ray tracing Dec. 26, 1914. Lateral view. Note slight depression in periosteal line of radius.

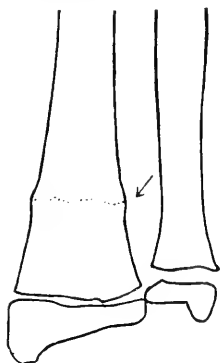

FIG. 2.

Children's Colles' Fracture.

X-ray tracing Dec. 26, 1914. Ant. post. view. Note slight bulging on either side of radius.

of the wrist, extending upward over the lower third of the radius. There were no ecchymosis and no crepitus. There was considerable tenderness on pressure over the lower end of the radius.

The diagnosis before a radiograph was taken lay between sprained wrist, separation of the lower epiphysis of the radius and sub-periosteal fracture. A radiograph showed a sub-periosteal fracture at the lower end of the radius. The antero-posterior view showed slight bulging spoken of above on each side of the lower end of the radius, about one inch above the lower end of the diaphysis. The lateral view, as is usual in these cases, showed a depression plainly in the periosteal line at the point of fracture.

Perfect recovery followed the usual treatment, as would be expected.

SEPARATION OF THE EPIPHYSIS OF THE FIRST METACARPAL BONE.

This bone develops by two centers, one for the shaft and one for the epiphysis, which is at the proximal instead of the distal end, as in the other metacarpals. I have recorded three cases of separation of this epiphysis.³ The diagnosis is not easy without an x-ray. It may be confounded with the Bennet fracture or the "punch fracture," by which is meant a transverse fracture of the metacarpal just above the epiphyseal line, and which displaces the epiphysis with the

lower fragment of the diaphysis. The importance of a radiograph in cases of injury to the thumb where there is question of these lesions is self-evident.

FRACTURE OF THE CARPAL CUNEIFORM.

This is a very rare injury. I have a record of one case, and knowledge of two others, only, one of which was successfully operated on and the fragment causing trouble removed. I have not found any cases in modern works on fracture. The case which I made this diagnosis in was treated for sprained wrist for some time without radiographs being taken. It illustrates well the importance of radiographs in all wrist injuries. There had been disability in this case for some months. After recognition of the fracture and immobilization for a considerable time, a good recovery was made.

In the lower extremity we will consider first, the separation of the lower epiphysis of the fibula, of which one example has come to my notice in a boy subject of fragilitas ossium. This boy had previously had fractures of the thigh, leg, arm and fingers,—six previous fractures in all. The injury was received in jumping from the porch to the ground, the right ankle turning under him. He was able to walk after the accident, but with a considerable limp. Physical examination showed the right ankle was swollen in the region of the external malleolus. There were no ecchymosis, no abnormal mobility, but there was a point seemingly sharper than normal felt in the region of the external malleolus.

The diagnosis before x-ray was uncertain. Sub-periosteal fracture of the lower end of the fibula, an ordinary fracture of the lower end of the fibula or sprained ankle, were considered. Separation of the epiphysis was not considered. The x-ray showed a separation of the lower epiphysis of the fibula. Treatment by plaster of Paris. Perfect union of the fracture in ordinary time, in spite of the condition of fragilitas ossium. It is of interest in connection with this case that the boy had the blue sclerotics, common in this condition of brittle bones, the incidence of which has been recently studied.

Fracture of the fifth metatarsal bone by inversion of the foot was first described by Robert Jones in 1902.⁴ Previous to that time, it was thought that such a fracture was impossible without direct violence. As in other fractures of this type, the diagnosis is the all-important thing, the treatment being generally a routine one. In the production of this fracture, the foot is inverted and the whole weight of the body may momentarily be borne across the foot on the fifth metatarsal. The following case is an example.

CASE 4. The patient, a well-developed woman, seen in August, 1913, slipped in a road at dusk, inverting left foot, so that weight was borne on its outer border. There were great pain and disability at once. Examination showed the outer border of the left foot swollen, a slight prominence at the

base of the fifth metatarsal, with some abnormal mobility. There was exquisite pain on pressure over this spot. There was no ecchymosis. Examination of the ankle was negative. An x-ray showed a transverse fracture at the base of the fifth metatarsal bone. Foot immobilized in plaster of Paris; crutches. Good result, but some pain off and on for some time after the fracture had united. Consideration of this fracture would not be complete without speaking of the occurrence of the Vesalianum or bone of Vesalius. It is excessively rare, but the possibility of its occurrence should always be thought of, in considering fracture of the base of the fifth metatarsal bone, as the radiograph of the Vesalianum gives the appearance of a fracture at the base of this bone, and the only positive way to be sure that we are not dealing with this rare abnormality is to have a radiograph of both feet taken when there is probability of this fracture.

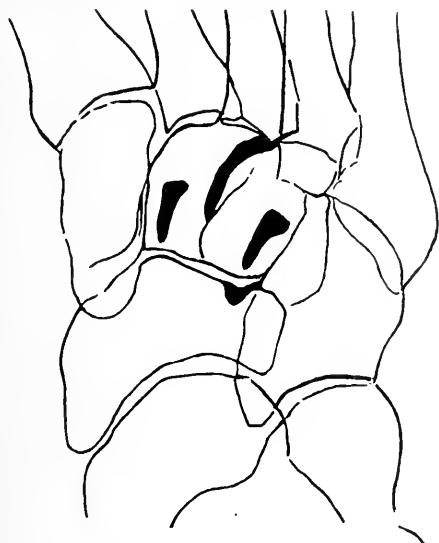

FIG. 6.

Fracture of Tarsal Cuneiforms.
(External and Middle.)

X-ray tracing Dec. 3, 1913. Antero-post. view. Fracture lines heavily shaded. Note chip off scaphoid also.

FRACTURE OF THE TARSAL CUNEIFORMS.

Fracture of the cuneiform bones of the foot is of extremely rare occurrence; probably almost as rare as the fracture of the carpal cuneiform. Only, as there are three cuneiforms in the foot and one in the hand, there is more chance of the possibility of a fracture. I have been unable to find an instance, excepting for the following case, for which I am indebted to my friend and colleague at the Boston Dispensary, Dr. Henry M. Chase, in whose service it occurred. Brief history is as follows:—

CASE 5. Male, 33 years. Seen at the surgical clinic of the Boston Dispensary, Dec. 3, 1913.

History of striking the right foot against the door two nights ago. Patient was sent to the Dispensary by the district physician.

Examination showed much pain over the cuneiform region; the foot was only slightly swollen.

Definite diagnosis absolutely impossible, without radiograph.

The foot immobilized; patient given crutches;

Dec. 5 the x-ray showed multiple fractures of the middle cuneiform and probably also of the external cuneiform, with a slight chip into the scaphoid also. Patient failed to report again for treatment.

It will be seen that in many of these cases of obscure and unusual fracture, treatment does not differ from that in routine cases; but the diagnosis is all-important. Lack of recognition of seemingly slight fractures, particularly subperiosteal, may lead to deformity, even though at the time they seemed trivial affairs. This is particularly so of the long linear cracks in the bones of the leg. If these fractures are unrecognized harm may result in weight-bearing, causing spreading of the fracture and subsequent static deformity. Fragments may break through the periosteum, excessive callus form and cause trouble. Children often complain of surprisingly little pain in subperiosteal fracture; often there is very slight disability. There is no crepitus with a pure subperiosteal fracture. In a few cases, such as the trochlea fracture recorded above, correct treatment is only operative, for the joint will never renew its normal functions while the fragment is in it; and failure to make a correct diagnosis will lead to permanent disability. Each recognized case of rare or unusual fracture leads to the recognition and successful treatment of others.

Medical Progress.

REPORT ON DERMATOLOGY.

By JOHN T. BOWEN, M.D., BOSTON.

TREATMENT OF LUPUS ERYTHEMATOSUS BY CARBON-DIOXIDE SNOW.¹

Hashund of Copenhagen has contributed an article on this subject to the *Annates*, which is of especial interest on account of the author's association with the Finsen Light Institute, in which cases of lupus erythematosus have been extensively treated by phototherapy.

He claims that the Danish physician Dethlefsen, in 1900, was the first to make use of the caustic effects of cold, in proposing to treat lupus vulgaris by means of chloride of ethyl; soon followed by others with methyl chloride, liquid carbonic acid, etc. Next came liquid air, used with success by Dade of New York. These methods all had the disadvantages of having a superficial and transitory action, which is limited

with great difficulty, and of being quite expensive. It was Pusey of Chicago who introduced carbon-dioxide snow for the same purposes, and developed an essentially practical method of far reaching application. This method is far less expensive than those that preceded it, and as a plastic snow is the agent employed, which may be moulded into various shapes, the surface of application may be strictly limited and the pressure be varied on account of the solid consistency of the blocks of snow. The fact that the snow has a higher temperature than liquid air is of minor importance. It is acknowledged that this method has been pursued for some years with success in America, and was introduced into Europe by E. Hoffmann.

At the start Pusey and Zeisler of Chicago recommended the employment of this method in the treatment of lupus erythematosus, and many writers soon published favorable accounts of their experience in this affection, some even going as far as to say that they had given up all other methods. Others were more reserved. Different methods of treatment have been proposed, that most frequently advocated being the application of the snow from 10 to 20 seconds. Haslund thinks that the various modifications of the technic have not improved on the simple procedure of Pusey's. Histologically the principal alterations caused by the freezing consist in a pronounced necrosis of the superficial layers of the skin, with partial obliteration of the vessels, followed by an inflammatory reactive process of rapid development.

At the time this article was written carbon-dioxide snow had been employed therapeutically in lupus erythematosus for somewhat more than two years. As the Finsen light had previously given moderately good results, although most often after a pretty long course of treatment and without being able to show a large number of complete cures, the snow was at first applied in a restricted way, combined with light treatment. Later, however, the snow was applied exclusively. Altogether about eighty cases were treated in this way. From the start the advantages of this method were recognized. No case was seen in which the method produced an aggravation of the trouble, as occurs when the Finsen treatment or other methods are employed.

Although the writer thinks that the time has not come to speak of definite results, the immediate action is considered as satisfactory as possible. The cicatrix is as smooth as that produced by the Finsen treatment. Different forms of the affection seem to react differently. The purely hyperemic varieties—those described by Bielt under the name "erythème centrifuge"—offer more difficulty to the production of bullae by the snow, and need stronger pressure than usual. These are the forms that sometimes extend a little in the course of treatment, or produce small new lesions at the edges of those already treated, and in which it is commonly advised to use mild

forms of treatment. As the snow is less irritating than most of the older remedies, Haslund employs it in these cases from the start, even when the hyperemic form is present.

On the whole Haslund considers that the treatment of lupus erythematosus by carbon-dioxide snow rivals that by the Finsen method, and one that will prove superior to all others. Its practical advantages are its simplicity, which enables it to be used without much annoyance or loss of time on the patient's part, and its extraordinary efficacy. The cosmetic result is also extremely good. In certain cases in which the results have been most favorable at first, the finishing touches may be hard to produce. Remnants may prove refractory to treatments and demand repeated application of the cold.

For these reasons phototherapy has been for the present abandoned at the Finsen Institute in the treatment of lupus erythematosus in favor of freezing by carbon-dioxide snow. This change of treatment has been based on a comparison of the results attained by the two methods. The patients who have received both methods of treatment have declared themselves impressed with the more favorable results produced by the freezing method. It is only fair to assume, however, that recurrences may take place after the freezing, as well as after other methods, but allowing for this, it represents a distinct advance over the older methods, and should be regarded as the method of choice.

TREATMENT OF CUTANEOUS TUBERCULOSIS AND THE "TUBERCULIDES" BY NEOSALVARSAN.²

Tzanek and Pelbois treated 21 patients by this method in Dr. Darier's service at the Hôpital St. Louis in Paris. These experiments were instigated by the fact that before the introduction of neosalvarsan, salvarsan had given interesting results in affections other than syphilis. Among these are included the protozoic affections, malignant tumors, pernicious anemia, chorea, psoriasis, etc. In most of these affections some good results have been attained, although often variable and doubtful. In the treatment of tuberculosis and the tuberculides favorable results have been reported by Herxheimer-Altmann, Bernhardt and Ravant.

The 21 observations, of which the details are given, concerned 9 cases of lupus, 2 of lupous ulcers, 1 of syphilitic tuberculosis, 2 of tuberculous gummata, 3 of suppurative adenitis, 2 of lichen scrofulosorum, 2 of papulo-necrotic tuberculides, 1 of erythema induratum of Bazin, 2 of lupus erythematosus, 1 of Boeck's sarcoid, 1 of Darier-Roussay's sarcoid.

With regard to the Wassermann reaction, the value of which has been recently questioned in some cases of tuberculides, it was found to be constantly negative when syphilis was absent, as well as Noguchi's reaction, which was performed at the same time, in almost all of the cases.

Intravenous injections were employed, in con-

centrated form, according to the technic of Dr. Ravant, without a single serious accident. The effect of the injections on the general health was uniformly good. During the course of the treatment the strength and appetite of the patients increased. While the local results were not constant, and while neosalvarsan cannot be considered as an infallible therapeutic agent in cutaneous tuberculosis, it was often of great value. In the cases of lupus, the results were characterized by a notable diminution of the erythema, a constant softening of the infiltration, and a more or less complete disappearance of the crusts and scales, three factors which make the subjects much more presentable. Furthermore, the patients who were treated by the x-rays and by scarifications showed a far greater improvement when neosalvarsan injections had been employed previously. It is admitted, however, that the injections were not sufficient to cause a complete disappearance of the lupus tissue, or in other words, a complete cure. In the cases of deeper-seated tuberculosis, however, (scrofuloderma) there was sometimes a complete cure.

The results in the cases of tuberculides were questionable and varying. One case of lichen scrofulosorum disappeared after three injections, and the same result was noted in a case of erythema induratum. Two cases of lupus erythematosus were much improved, and a sarcoïd was healed.

In conclusion it is asserted that cutaneous tuberculosis and the tuberculides may be greatly ameliorated by injections of neosalvarsan, either alone, or combined with tuberculin (method of Herxheimer-Altmann), but the latter procedure is insufficient, and must be supplemented by other local or general treatment, such as that by light, x-rays, radium, scarification, etc. Neosalvarsan shows its most marked results in the treatment of tubercular adenitis.

SOME CUTANEOUS EFFECTS OF RADIUM AND THE X-RAYS.³

In the French Société de Dermatologie et de Syphiligraphie on June 4, 1914, Jeanselme presented a woman who had been burned with sulphuric acid, five years previously. The burns were multiple, but for the most part superficial, and healed in less than two months. The cicatrices, however, were disfiguring, red and keloidal, and radium was employed with the hope of producing a better cosmetic effect. For a year three applications a week were made, taking care to filter the rays. Later, having been admitted to the hospital as an attendant, she began to make the applications herself, observing the rules prescribed for six months, afterward using them without filtering for four months. At the end of that time she developed a dermatitis, which obliged her to stop all treatment, the pain being very severe, for two months. There was found to be a very marked contrast between the islands of tissue subjected

to the radium treatment, and the parts not so treated. A large facial cicatrix and one on the wrist had been treated with special energy, and especially by the non-filtered rays. The keloidal appearance had been much improved and had even disappeared over large surfaces. In these places the cicatrix was extremely uniform, and of a pronounced white color, but surrounding it were deeply pigmented areas, of a bistre or sepia color. Here and there was a network of dilated capillaries of a bright red color. A cicatrix in the pectoral region, which had received only a few non-filtrated rays, showed still in part a raised keloid; but the pigmented spots were light in color, and there was only a suggestion of dilated vessels. A cicatrix of the shoulder, that had not been treated by radium, had a decidedly keloidal appearance, although there had been some spontaneous retrogression. There were no pigmentation, nor telangiectasis. In a word, the cicatrices following a sulphuric acid burn had diminished, little by little, without active treatment, while the appearances that had followed a dermatitis produced by radium were most disfiguring.

Replying to a question by Jeanselme as to what could be done to ameliorate these disfigurements caused by radium dermatitis, Pautrier replied that he had had much experience with attempts to improve the pigmented scars and telangiectases caused by the application of x-rays to produce epilation, a procedure that he strongly condemns, since complete epilation by x-rays can never be attained without cutaneous lesions; he has frequently seen late reactions, occurring a year or a year and a half after the applications. For treating these deformities he has tried scarification, electrolysis, and the fine-pointed galvano-cautery. The results were mediocre and slow. Perhaps the best results were from the filiform douche, which must be used with strong pressure.

At the same meeting Jeanselme exhibited another case, that of a woman of 28 years, who had had for six or seven years, enlarged glands in the carotid region, especially on the left side. There were also enlarged glands in the submaxillary, submental and axillary regions. On the left side of the neck there is a large "erectile" surface covered with interlacing telangiectases, with some detached foci at the periphery. The patient asserts that these vascular changes are not congenital, but began to appear six years previously, when she was undergoing treatment by the x-rays for the enlarged glands.—a treatment that was continued through a whole year, with the result that the glands were much diminished in size. The treatment was suspended after a year, however, because of the appearance of a cutaneous erosion, which was followed by superficial scars and by vascular hypertrophy. The first of these telangiectases, which were present in detached "islands," had appeared two months after cessation of the treatment and they had continued to increase

CHALK PASTES.

Unna⁴ refers to the prominence in dermatological therapeutics that has been occupied by chalk, since it was incorporated in Wilkinson's ointment for the cure of scabies. Later, Hebra, Jarisch and others lessened the amount of chalk in this prescription, also used in pruritic eczemas, and other obstinate skin affections, until its importance was rendered negative. In 1884 Unna proposed the addition of chalk to the old mixture of linseed oil and lime water, a household remedy for burns, as improving its consistency. The advantages of this composition are that the weak alkali of the lime water saponifies a small part of the oil, which then holds the rest of the oil in emulsion, and this emulsion on account of its property of mixing with water, allows evaporation from the skin, hence its cooling effect. A further advantage is that cooling basic substances, such as lead water, may be added to it, and the consistence of a paste is attained by the addition of the chalk, or of bicarbonate of soda, or zinc oxide. The following formula was recommended.

Ol. lini.
Aq. calcis 5ā 20.
Cretae.
Zinci oxydati, 5ā 30.

This mixture he called Pasta Zinci Mollis, belonging to the group of cooling pastes, which are not only drying, but also cooling. Its indications are weeping eczemas of the genitals and of the head, burns of the second degree, and toxic cutaneous inflammations produced by iodiform, sublimate, chrysarobin, pyrogallol, etc.

Although at first the large amount (30%) of chalk in the Pasta Zinci Mollis was employed solely to increase the consistency, experience soon showed that it had a marked effect in increasing the analgesic properties of the basic reacting lime water. It is noteworthy that the disinclination of all surgeons since the era of Listerism, to employ the linseed oil and lime water liniment in burns has not been able to banish this remedy from popular application, on account of the analgesic action of the lime water combined with the analgesic and slightly reducing effect of the linseed oil. None of these properties are possessed to any extent by modern antiseptics.

A new employment of the chalks has been devised by Unna by combining them with mucilage of gum arabic in the following proportions:

Calcium carbonicum	40
Zincum oxydatum	20
Mucilago gi. arabici	20
Glycerin	10
Aqua calcis	10

To this may be added a small amount of thymol, or menthol, to keep it. As it hardens on exposure to the air, it should be kept in tubes. This forms a homogeneous paste, which leaves

upon drying a firm dry mass upon the skin. It combines the anti-inflammatory and analgesic action of the basic carbonate of calcium with the drying and absorbent properties of the gum pastes. The chief indication for this paste is the rapid drying up of large edematous, erythematous and oozing surfaces. Severe edema of the face, neck, and extremities in the course of chronic eczema is a condition specially suited for the paste, situations which have hitherto been treated by thick layers of meal, talcum, carbonate of magnesia, etc. There is usually speedy improvement in 24 hours, whether the inflammation has a physical causation, such as heat, sun's rays, cold, or has been produced by chemicals, as chrysarobin, pyrogallol, resorcin, etc. A second indication, of great importance, is the chance to dry up all fat salves and fat pastes by covering them with the chalk paste. This is especially valuable in the case of very irritating applications, such as chrysarobin, as it limits the secondary inflammatory action upon the adjacent parts of the skin.

A third indication for the chalk paste is to keep the skin dry about wounds, oozing skin affections, and fistulae. It tends to check the extension of progressive inflammations, the spread of the organisms of pus and of erysipelas, and of toxic, bullous dermatitis. It is valuable especially in the first stages of vesicular and weeping eczemas, until a certain degree of drying has been attained, and in varicose ulcers of the lower leg, complicated with eczema. The pastes are not to be rubbed in hard or for a long time, but simply spread lightly over the skin, when they dry quickly. The paste is to be re-applied in places from which it has come off, from friction of the clothing, from perspiration, or from oozing, and this may be done once or more a day, according to the need.

SKIN DISEASES IN THE AMERICAN NEGRO.

Hazen⁵ of Washington, who has had abundant opportunity for observing skin diseases among the colored portion of the community, has summarized his observations, based entirely upon personal observation. Howard Fox has previously written on the subject, his statistics being obtained from the clinics at Johns Hopkins Hospital and from the Central Dispensary in Washington. The cases on which Hazen's paper is based were 2000 in number, and were observed partly in Dr. Gilchrist's clinic at the Johns Hopkins Hospital, partly in the medical clinic at the Children's Hospital in Washington, but chiefly in the dermatological service at the Freedmen's Hospital in Washington. Out of the 2000 cases, 718 were full-blooded negroes, and 543 had much more negro than white blood; the remaining patients were mulattoes, that is the white blood either predominated or was about equal in amount to the negro blood.

It was found that acne vulgaris was about as common among negroes as among whites, con-

trary to the belief of Howard Fox, and that there was little difference in its response to treatment. It is most interesting to note that the milder type of skin cancer is almost unknown among negroes, and the more malignant type is also rare. Also, the so-called precancerous lesions, especially the seborrheic warts, are very rare among the colored, the pigment probably acting as a preventive, as Hyde believed. On the other hand, chloasma, keloid, and vitiligo are, as has been known for a long time, much more common in the negro. Hazen refers to two remarkable cases of vitiligo, in which the loss of pigment developed within 24 hours, there being marked constitutional disturbance at the time. In another case spilling of hydrocyanic acid on the skin seemed to be the exciting cause, as the lesions appeared at the point of contact of the acid.

With regard to the production of x-ray dermatitis, the x-ray operators in Washington agree that the negro skin is much less easily affected than the white. Eczema is less common among the colored, and seems to respond more readily to treatment. When present it is apt to be of the papular and squamous types. Erythema multiforme, furuncle, and impetigo contagiosa are all less frequent in the negro, as well as lichen planus and lupus erythematosus. "Moles" and port wine marks are very uncommon in the negro, and singularly enough the same is true of pediculosis capitis, though pediculi in other situations are equally common in the two races. Hazen and Fox agree that psoriasis is much less common in the negro, but when present runs about the same course as in the white. Hazen, contrary to Fox, considers scabies more common among the colored.

The skin of the negro is naturally very oily and the face is more greasy than that of the average white person, but with regard to seborrhea, we do not often find the yellowish patches on the chest or back, nor the acute forms of so-called seborrheic dermatitis. Yet the dry type is frequently seen both on the face and body. On the face the lesions are white and scaly, and form rings which are very chronic, often causing temporary loss of pigment when the scales disappear.

Practically all authors agree that syphilis is more prevalent in the negro race, a fact not to be wondered at considering their environment. Yet extragenital chaneres are very rare. In ten years Hazen has seen but one, and there has not been a single case in five years at the Freedmen's Hospital. Also macular and maculopapular syphilides are uncommon, which cannot be explained by the color of the skin concealing the eruption, since they are just as rare in mulattoes as in full-blooded negroes. Papular syphilides, on the contrary, are very common, and especially the large papular type, as are also

condylomata. Tertiary syphilis is not more common among the negroes, in proportion to the total number of cases of syphilis. Ringworm of the scalp is more common than among the whites, as is also urticaria, both of the ordinary and of the so-called "giant" type. Hazen remarks that in a majority of the cases of urticaria it is possible to get a history of a heavy indulgence in cabbage as the cause of the outbreak. Tuberculosis of the skin in any of its forms is just as common in one race as in the other, which is surprising when one considers how common pulmonary tuberculosis is in the negro.

ECZEMATOID RINGWORM, PARTICULARLY OF THE HANDS AND FEET.

Hartzell⁶ relates several instances of the form of ringworm described recently by Sabouraud, as occurring especially between the fingers and toes. The first case was that of a youth of 17, who had an inflammation of the skin of the outer side of the left leg. The inflamed area was about the size of the palm, quite ill-defined at its borders, slightly scaling, and somewhat itchy. It had existed for about a month. Microscopic examination of the scales showed numerous mycelial threads, and the affection rapidly disappeared under the use of a parasiticide ointment. This patient had formerly had an extensive ringworm of the scalp which had lasted until he was 15 or 16 years of age.

The second case, that of a woman of 50, had an obstinate affection of the skin of the plantar surface of the toes of both feet, which consisted in an unusual dryness, with slight fissuring, scaling, and some itching, which had lasted a number of years. It resembled mostly a mild squamous eczema and had been treated by numerous kinds of ointments and lotions, together with the x-rays, without especial improvement. Mycelium in small amount was found under the microscope, and a complete cure was effected by the use of parasiticide ointments.

The third case is that of a man of 24 who had suffered for three or four months with an affection of the skin of the toes of both feet, characterized by redness, scaling, and fissuring in the flexures and between the toes, accompanied by moderate itching. It was slowly spreading backward upon the soles, and had first appeared while the patient was in Panama. Mycelium was found microscopically and a cure was quickly attained by a parasiticide ointment.

The fourth case was that of a youth of 17 who had a chronic inflammation of the sides and palmar surface of the right index and middle finger, with a portion of the palm adjacent. It looked like a mild scaling eczema, for which it had been mistaken, but mycelia were demonstrated in the scrapings. He said that he had had a ringworm of the axilla and thighs the previous summer.

Hebra, more than fifty years ago, described a peculiar form of dermatitis which occurs on the inner surface of the thighs, and on the scrotum, accompanied by itching and scaling, sometimes by oozing and crusting. It had many of the appearances of eczema, and he therefore gave it the name of eczema marginatum, on account of the usually sharply defined border. Later Köbner found mycelial threads, which established its parasitic nature. This affection has long been familiar to dermatologists, who have recognized that it was not a true eczema, although resembling it. Sabouraud has called attention to the frequent occurrence of eczematoïd inflammation of the hands and feet, and particularly of the fingers and toes, which he found was caused by the same fungus that causes the eczema marginatum of Hebra. The latter had been universally regarded as an unusually inflammatory form of ringworm, caused by the same organism that causes the ordinary forms, the greater degree of inflammation being due to the heat, moisture and friction due to the situation. Hebra, however, had noticed that when the hairy parts were attacked by eczema marginatum, no changes were produced in the hairs; they retained their color, did not lose their glossy appearance, fall out, nor break off, and no one had ever succeeded in demonstrating the presence of fungus in the hairs. Sabouraud found that these eczema-like forms of ringworm are produced by an organism that differs botanically from all the forms of ringworm, so that it may easily be demonstrated under the microscope. He has called this fungus the epidermophyton inguinale, and shown that it differs from all the ringworm fungi, not only microscopically, but also culturally, and unlike the trichophyton does not invade the hair, but only the upper layer of the epidermis.

Hartzell asserts that this form of parasitic eczema undoubtedly occurs very frequently, as will be found when it is suspected in every case of eczema of the fingers and toes. Sabouraud says that eight out of every ten cases of so-called intertrigo of the toes are actually parasitic, the result of infection with the epidermophyton fungus, and that many of these cases have been preceded by eczema marginatum of the groin or axilla. The affection is more common in the well-to-do classes. Hartzell has found the ointment that was suggested by Whitfield, viz., one containing 3% of salicylic acid and 5% of benzoic acid most effective, but that it must be used with caution in very inflammatory cases, as it sometimes causes much irritation.

Reports of Societies.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

MEETING OF THIS SOCIETY HELD JANUARY 19, 1915, AT THE BOSTON MEDICAL LIBRARY. The President, DR. GEORGE L. RICHARDS IN THE CHAIR.

A paper was read by DR. GORDON BERRY entitled

LABYRINTHITIS FOLLOWING OPERATION FOR ATRESIA.*

DISCUSSION.

DR. JOHN J. HURLEY emphasized the fact that in this case the atresia was only an incident and had no connection with subsequent events.

He approached the subject with considerable trepidation in view of the fact that such an authority as Dr. Cushing had been consulted in the matter. In the light of the very accurate details presented by Dr. Berry, Dr. Hurley presented the following proposition: That never at any time from start to finish, was this a case of labyrinthitis.

In defense of this proposition Dr. Hurley made the following points:—

1. If it is claimed that this is a case of labyrinthitis which is causing these symptoms, it must be clear that if we eradicate the labyrinth, the symptoms should disappear. But we have eradicated the labyrinth under the most aseptic conditions, and the symptoms not only do not disappear but grow worse. Unless we are ready to meet the first principle of logic, the principle of cause and effect, we must reject the labyrinth as an etiological factor in the case.

2. Dr. Hurley called attention to the fact that not one symptom in this case was traceable to the following cranial nerves: 1st, 2nd, 3rd, 4th, 7th, 11th and 12th.

3. On the contrary, every symptom was traceable to the following cranial nerves: 5th, 6th, 8th, 9th and 10th. Even if the labyrinth had not been ruled out already, there is no labyrinthine condition which could have involved all these nerves. The conclusion is inevitable, that the etiology must be sought for at a point where these nerves are in close proximity, much as one makes a diagnosis of hemorrhage in the internal capsule.

Where are the nerves so converged? At one point only, the cerebello-pontine angle. Dr. Hurley said that the symptoms, viz., nystagmus, vertigo, nausea, vomiting, incoherent speech, delirium and paralysis of the external rectus, all pressure symptoms, could have their origin in pressure at this point only.

4. What could cause pressure at this point? Tumor ruled out by shortness of duration and gumma by negative Wassermann. Cerebellar abscess ruled out by absence of all signs of suppuration, negative temperature, negative spinal fluid, negative blood.

5. Lumbar puncture always relieved symptoms. For a month after operation, cerebrospinal fluid escaped from the wound, which was purposely kept open and during this time there were no symptoms. At the end of the month the wound was allowed to close, thus stopping escape of spinal fluid, and this was immediately followed by return of symptoms in aggravated form.

* See JOURNAL, page 700.

6. On making a lumbar puncture, the fluid was normal in appearance, but escaped under higher pressure than normal.

7. Taking into account the foregoing six points, Dr. Hurley submitted that if it could be demonstrated that a condition of increased pressure of the cerebrospinal fluid could be imagined, which focused the pressure on the 5th, 6th, 8th, 9th, and 10th cranial nerves, the diagnosis in this case would be established.

8. Such a condition does exist, and the train of symptoms arising therefrom is the latest work of Barany of Vienna, and is known as Barany's symptom-complex.

9. Dr. Hurley showed by a sketch on the blackboard that the 5th, 6th, 7th, 8th, 9th, and 10th cranial nerves took origin from the floor of the pons and the lateral cisterna and radiated outward through the cisterna. An adhesion at this point would cause a cyst of the lateral cisterna, and the increased pressure would be demonstrated by focal symptoms on the above nerves, with the exception of the facial (Portio dura) which would not be affected unless the pressure was enormous. The 1st, 2nd, 3rd, 4th, 11th and 12th nerves would not be affected, as they do not run through the lateral cisterna.

10. Dr. Hurley considered the case an inflammatory cyst of the cisterna pontis lateralis, with the following symptoms from pressure: 5th nerve, occipital headache; 6th, paralysis of external rectus; 7th, no symptoms; 8th, tinnitus, disturbance of hearing, nystagmus; 9th, nausea and vomiting, vertigo; 10th, partial paralysis of the tongue, incoherent speech.

11. Prognosis, good.

12. Treatment, medical. The use of drugs, such as atropine and calcium lactate, to cut down the secretion of cerebrospinal fluid. Failing in this, surgical methods to do the same. Lumbar puncture and decompression through the mastoid, elevating the dura on the posterior surface of the petrous portion of the temporal bone, breaking into the cerebrospinal circuit at the aqueductus vestibuli.

DR. D. HAROLD WALKER: I never before heard of a case just like this one. Dr. Hurley's description of Barany's symptom-complex interests me. I thought, when Dr. Berry gave me a memorandum of his case, that it might be one of that kind, one where there are adhesions formed in the cerebellar fossa, causing localized areas, the drainage of which is obstructed, and causing variations in the flow of perilymph through the aqueductus vestibuli.

DR. E. A. CROCKETT: On looking over Dr. Berry's notes on this case, I came to the conclusion that it was a case of cerebellar abscess, and I hope that Dr. Berry will report again on this case a year hence.

I do not believe there ever was a suppurative process in the middle ear. It is, I think, a congenital lesion. I do not think that the labyrinthine operation was necessary. On further considering the Barany symptom-complex and hearing Dr. Hurley's careful analysis, I feel that possibly I would give up my earlier diagnosis of cerebellar abscess.

DR. GEORGE A. LELAND: I had the pleasure of hearing and reading Barany's paper on the development of his symptom complex, which he presented at the International Medical Congress in London a year and a half ago. On hearing Dr. Berry's paper, it struck me that there were many symptoms conso-

nant with Barany's. I do not think we can make a definite diagnosis from the paper as read this evening so much was omitted. There arises the question of tenderness of and behind and below the mastoid, sometimes present, sometimes not; also the combination of vertigo, nystagmus, tinnitus, nausea, disturbance of speech should be noted, whether nystagmus was of long or short duration, and quickly or slowly excited by the caloric test. These symptoms have much to do with the question, especially if they are not constant. Where there is a transient paralysis of the 6th; where there is variation of the symptoms with the amount of pressure of cerebrospinal fluid, that is, diminished by its subsiding; also including such irrational symptoms, smashing things, unaccustomed violence, probably loss of memory for very recent events; things which he would do he does not do, or he does things he knows better than to do and then he forgets he has done them. Perhaps he would complain of headache and then deny it a few hours afterwards. These would point to intracranial pressure which was interpreted by Dr. Cushing as internal hydrocephalus, or serous meningitis. This intracranial pressure, as I look upon it, may also be caused by a dilated cisterna, as Barany has shown, though he did not mention such a transient change of disposition in any of his cases, as I remember at the moment.

DR. F. P. EMERSON: I quite agree with Dr. Crockett that the evidence all points to an atresia of the canal that was of congenital origin. In a differential diagnosis of the form of labyrinthitis present, it would seem as though we could exclude every form except that of a serous diffuse labyrinthitis. The fact that the vestibular reaction was still present would exclude the diffuse manifest or latent forms of purulent labyrinthitis. Some cases have been reported in which during the granulating stage following a radical operation a fistula was formed. This might account for a serous labyrinthitis, as it did not apparently come on during the first three days following operative interference, as we would expect. I am inclined to believe that there was a serous meningitis present, but whether it was secondary to a focus in the labyrinth or cerebellum, I do not think we can tell. Dr. Berry is entitled to a great deal of credit for reporting such an obscure and interesting case.

Book Reviews.

Evolution of Sex in Plants. By JOHN MERLE COULTER. Chicago: University of Chicago Press. 1914.

This monograph from the department of botany of the University of Chicago presents a valuable microscopic study of the evolution of sex in the vegetable kingdom. The author considers that the significance of sex differentiation lies in the fact that it makes organic evolution more rapid and more varied. The book is illustrated with forty-six figures in the text and forms a valuable contribution to the philosophy of evolution.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, MAY 13, 1915

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p.m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

CONSTRUCTION OF LOCAL TUBERCULOSIS HOSPITALS.

THE attention of the medical profession of Massachusetts is called to House Bill 2088, a petition introduced by Representative George M. Worrall of Attleboro, which asks for a year and a half extension of time within which cities and towns shall construct tuberculosis hospitals. This was introduced under suspension of the rules and referred to the Committee on Public Health.

In 1911 the so-called Tuberculosis Hospital law was passed after long and grave consideration of the tuberculosis situation in this state. This law is to the effect that every city shall construct and maintain a local tuberculosis hospital for the care of advanced consumptives within its midst. At the request of the State Department of Health towns also may be included

within this law. This law is an eminently wise and sane one. At the present time, out of thirty-five cities in Massachusetts, sixteen have complied with it. In addition to these there are two town hospitals, Clinton and Westfield, and one county hospital, the Hampshire County Sanatorium. The present Legislature has made an appropriation to build another county hospital, in Barnstable.

The bill under consideration has the strong backing, as is naturally to be expected, of senators and representatives coming from districts in which there is no local tuberculosis hospital and which wish to evade spending the money to provide one. The State Department of Health has given to such cities until September 1st of this year to comply with the law. At the end of this period the matter will be put in the hands of the Attorney-general to see that it is properly enforced. The present bill nullifies this act of the State Department of Health and allows an extension of time until January, 1917. This is a distinct injustice to those cities and towns,—Boston, Cambridge, Chicopee, Clinton, Fall River, Fitchburg, Haverhill, Holyoke, Lawrence, Lynn, New Bedford, Pittsfield, Somerville, Springfield, Salem, Westfield, Waltham, and Worcester,—that have complied with this law. It continues for two years more the handicap under which our state sanatoria are now laboring, namely, that our beds are kept filled with patients in the advanced and dying stages of the disease, who, in justice to themselves and their friends, should be cared for in local hospitals near their friends and relatives, while in addition it prevents the state from caring promptly for those patients, for whom our sanatoria are primarily intended, in the incipient and favorable stages of the disease.

Furthermore, this law, if passed, will extend for a year and a half the time in which cities and towns of 10,000 inhabitants and over must equip and maintain a local tuberculosis dispensary. The act requiring such dispensaries was passed in 1911, at the same time the one requiring tuberculosis hospitals was enacted. The State Department of Health has given cities and towns coming under the provisions of this act until July 1st of this year to comply with it. The establishment throughout the state of such dispensaries as this will be one of the greatest steps in advance in controlling and eradicating tuberculosis from our midst. This law, if passed, will delay this good work over eighteen months.

If passed, this law will constitute a distinct backward step in health matters in Massachusetts. Every physician is urged to see his representative and to use all the influence he has to oppose the passage of this act.

HEALTH CONDITIONS IN PANAMA.

THE penalty the Caucasian has to pay for attempts to conquer lands with unsuitable climatic conditions is exemplified in the Canal Zone, as shown by the recent reports of Lieut. Colonel Charles F. Mason, chief health officer.

In his annual report, covering 1914, he shows that among the negroes the hospital record was 191.93 per thousand, while among the whites it was 523.63, or nearly three times as much. Also the number of laborers constantly non-effective among the whites was 23.20 per thousand, while among the blacks this was only 10.16, or less than half. The latest report from that region, that for February, 1915, gives substantially the same figures, the non-effective rate for whites being 22.55 and that for blacks 8.58 per thousand.

A consolation which it offers, however, is the comparison of the death rate per thousand. During 1914 this was 3.13 for the whites and 4.63 for the blacks, which would seem to show that although the sick record for the Caucasian transported to an alien climate may be twice as high as that of the native population, his vitality is also greater. The above discrepancy may be also explained by the fact that the non-effective list is largely made up of those placed *hors de combat* by malaria, for which the death rate is relatively low.

General health conditions in Panama and the Canal Zone appear to be improving, as evidenced by the diminution from month to month of the number of cases admitted to hospitals. For example, in February this was 294.17 per thousand, as opposed to 332.87 in January and 437.70 in December. This decrease is undoubtedly due to the education of the native population in prophylactic measures by Dr. Mason and his assistants. Throughout the Canal Zone the school children in the higher grades are being taught

the rôle of the mosquito in the transmission of disease. During 1914 all the school children in Panama, Colon and the Canal Zone were vaccinated, with "takes" varying from 60% to 80%.

Among other measures looking to the conservation of the public health might be mentioned the institution of an annual physical examination of all gold employees in this region. Also it has been made compulsory for laborers employed by the government to take quinine for at least a month after an attack of malaria.

The incidence of this latter disease shows a steady decrease and it is also gratifying to note that the death rate for malaria was reduced more than 50% in 1914.

The death rate per thousand in Panama City for 1914 was high, 32.85, but this is understandable when we observe that half the deaths were of children under five years and due largely to gastro-intestinal disorders, the results of maternal ignorance.

Dr. Mason comments on the little known clinical fact that the negro race is much more susceptible to primary pneumococcic infection of the sinuses and the middle ear than the white, also upon the prevalence in this race of obliterative syphilitic endarteritis, especially in the West Indian negro laborers. He remarks that there seems to be widespread luetic infection among this class of employees.

MILK LEGISLATION IN MASSACHUSETTS.

IN the issues of the JOURNAL for February 25 and March 25 we commented editorially on the labor clean milk bill, then and now still pending before the Massachusetts General Court. This bill has recently passed the Senate and had been ordered to a third reading in the House. Unfortunately, however, at this juncture, as a result of the determined and persistent opposition of the Massachusetts State Grange, a substitute measure was introduced giving power to the department of animal industry, to control all milk inspection by the State Health Commissioner. The text of this pernicious substitute is as follows:—

"The state department of health and boards of health in cities and towns shall have authority to prohibit the shipment, sale or delivery of milk, skim milk or cream under conditions which, in their judgment, are detrimental to public health. In case they decide that milk, skim milk or cream from any dairy is produced under such conditions, they shall give written notice of their finding to the producer thereof and also to the department of animal industry, and the sale, shipment and delivery of all such milk, skim milk, or cream shall thereupon cease, and it shall be the duty of the department of animal industry to inspect the dairy and to require such changes and improvements as to the circumstances under which the milk, skim milk or cream is produced as shall be approved by the state department of health or by the local board of health making the complaint.

"It shall be unlawful for any person to ship, sell or deliver milk produced in any dairy to which the above notice has been given by the state department of health or by any local board of health until a certificate has been filed by the department of animal industry with the state department of health or local board of health, as the case may be, stating that such improvements have been made as were required by the department of health or by the local board of health, as the case may be, and as will make the production of milk in the said dairy safe and sanitary.

"Whoever ships, sells or delivers milk, skim milk, or cream in violation of the provisions of this act, shall be punished by a fine of \$100 for each offence."

The purpose of this substitute measure was obvious, to place in the hands of the bureau of animal industry the essential control of the milk producing industry in this state. Such a measure would absolutely thwart the purpose of the proposed milk legislation for which so vigorous a conflict has been made for a number of years and which, at last, seems on the verge of successful enactment.

Fortunately, on May 3, this new substitute measure met with the unqualified defeat which it deserved, and the labor clean milk bill was ordered to be engrossed by a vote of 149 to 68.

On May 6 the bill, having been returned to the Senate, was by that body amended with a clause exempting railroads and other common carriers from the provisions of the act. With this amendment it is again before the House for final consideration. It is earnestly to be hoped that the ultimate passage of this bill and its approval by the governor may at last establish reliable and adequate methods of milk inspection and control in Massachusetts.

OUT-PATIENT CLINICS FOR MENTAL DISEASE.

THE recently published bulletin (No. 8) of the Massachusetts State Board of Insanity for April, 1915, contains a striking statement of the number of persons who, during the first quarter of this year attended the new out-patient clinics which are being established throughout this state in connection with the various hospitals for the insane. During this period the total number of patients visiting this clinic at the Worcester State Hospital was 106, at the Taunton State Hospital, 99; at the Northampton State Hospital, 78; at the Danvers State Hospital, 91; at the Westborough State Hospital, 7; at the Psychopathic Department of the Boston State Hospital, 1054; at the Gardner State Hospital, 9; at the Monson State Hospital, 12; and at the Massachusetts School for Feeble-minded, 120; making a total of 1576 patients who availed themselves of this valuable opportunity for examination, observation, advice and treatment. The clinics were held on stated days, sometimes at the several hospitals, sometimes on circuit in the larger neighboring cities. The establishment and successful operation of these clinics as evidenced by the above data is not only a valuable service in the prophylaxis of mental disease and the interests of public health, but is of significance as indicating so strikingly the progressive change in popular attitude towards chronic disease of this type from that which formerly prevailed.

THE HEART MUSCLE IN PNEUMONIA.

PRELIMINARY announcement is made from the physiologic laboratory of the Harvard Medical School of an important piece of research on the heart muscle in pneumonia by Dr. L. H. Newburgh and Dr. W. T. Porter, as follows:—

"When a cannula is tied into the descendens or the circumflex branch of the left coronary artery of the dog, and the part of the ventricle nourished by the artery is cut out, the piece of ventricle will beat for hours if supplied with warm defibrinated blood under moderate pressure.

1. In our experiments the left ventricle from 10 normal dogs, perfused with normal blood, contracted an average of 181 minutes. The

area covered by the ten contraction curves (a measure of the work done by the ventricular segment) weighed 8.84 grams, an average of 0.88 grams.

2. Exactly similar preparations from 10 dogs that *had died* of pneumonia contracted an average of 200 minutes and their contraction areas weighed 8.50 grams, an average of 0.85 grams. These ventricles were perfused with normal blood.

It is evident that the heart muscle is not impaired in pneumonia.

3. Similar preparations from 10 normal dogs, in which the ventricular muscle was fed with blood from 10 dogs near death from pneumonia, contracted an average of 70 minutes, and their contraction areas weighed 3.40 grams, an average of 0.34 grams.

This demonstrates that pneumonia blood lowers the contractility of the heart muscle, though the ventricle is ready to beat normally as soon as its food is normal.

4. Seven ventricles from dogs about to die from pneumonia were perfused with pneumonic blood from the same pneumonic dogs. These ventricles beat an average of 185 minutes and the contraction areas weighed an average of 0.69 grams.

This demonstrates that the heart in pneumonia largely adjusts itself to its poisoned food supply.

L. H. NEWBURGH, M.D.,
W. T. PORTER, M.D."

MEDICAL NOTES.

AWARD OF JACKSONIAN AND TOMES PRIZES.—It is announced that the Royal College of Surgeons of England has awarded its Jacksonian prize to Mr. Jonathan Hutchinson for his essay on the pathology, diagnosis and treatment of trigeminal neuralgia, and the John Tomes prize to Mr. J. F. Colyer for his work on comparative dental anatomy and pathology.

TYPHUS FEVER AT NEW YORK.—Report from New York states that on May 1, a case of typhus fever was discovered aboard the Greek steamer *Christoforos* which arrived in New York Harbor that day from Marseilles. The patient, a Greek, has been isolated and the vessel has proceeded to its destination at Baltimore. The case had been discovered on board ship on April 20 and had been isolated since that time. It is stated that following the second Balkan War twenty cases of typhus fever, similarly originating in Marseilles, were thus brought to the port of New

York and were all safely detained at quarantine. On May 4, a second case of typhus was found on board the Cunard liner *Carpathian* sailing from Naples, Genoa and Piraeus. The patient was removed to the Swinburne Island Hospital for treatment. The steorage of the ship will be fumigated.

REPORT OF THE BOARD OF HEALTH OF THE TOWN OF MONTCLAIR, N. J.—The recently issued report of the board of health of the town of Montclair, covering the period from Jan. 1, 1914 to December 31, 1914, shows that the death rate for the year was the lowest in the history of the town, being 9.37 per 1,000 inhabitants. The birth rate, 18.8 per 1,000 inhabitants, is the lowest recorded for the town although it is the same rate as for the previous year. The marriage rate was 7.1 per 1,000 inhabitants.

RED CROSS SURGEONS SAIL FOR EUROPE.—On May 1 a number of American surgeons sailed for various parts of Europe for service in the Red Cross. Dr. Dunlap Pearce Penhallow of Boston, a major in the medical corps of the Massachusetts volunteer militia, has been granted six months' leave of absence and expects to be stationed in a hospital in France. Dr. Herbert H. Howard, whose appointment as staff physician in the Women's Relief Hospital at Paignton, England, has been noted in a previous issue of the JOURNAL, sailed in the same party.

Two surgeons are assigned to Serbia, Dr. Shadworth O. Beasley of San Francisco, graduate of Cooper Medical School and lately of the medical department of Leland Stanford, Jr., University and Dr. W. A. Jolley of Boulder, Col., graduate of Jefferson Medical College.

Dr. Walpole Brewer, of Tuskegee, Ala., graduate of Vanderbilt University Medical Department, has been assigned to Vienna.

On the steamship *Rotterdam*, bound for Rotterdam, were Dr. R. H. Crawford and four nurses, who are going to Germany.

Dr. Alden R. Hoover, head of the American Board Mission Hospital at Cesarea has been recalled from a furlough in this country, to begin relief work against typhus among the Turks. He expects to be engaged with the Turkish Army. The American Board Mission Hospital at Cesarea is a well equipped institution with eighty beds and had about 1,000 patients last year.

AFFILIATION OF COLUMBIA UNIVERSITY AND PRESBYTERIAN HOSPITAL.—Report from New York on May 4 states that plans are announced for a new medical school to be erected jointly by Columbia University and the Presbyterian Hospital, on the former site of the American League baseball grounds on the upper West Side, at an expense of \$10,000,000. Columbia will contribute \$7,500,000 to the project, it is

stated, and five years has been fixed as the limit of the period for raising the total sum. The Presbyterian Hospital purposes to erect a large hospital building, into which it will move from Madison avenue and Seventieth street. The College of Physicians and Surgeons will move to the new site from its buildings at Fifty-ninth street and Amsterdam avenue. The ability to raise the fund necessary for the purpose is the only undecided part of the plan.

HEALTH OF NEW YORK CITY BETTER THAN LAST YEAR.—The number of deaths reported last week from all causes was 1638, with a death rate of 14.72 per one thousand of the population, as against 1593 deaths and a rate of 14.89 during the corresponding week of 1914. There were 154 deaths reported from lobar pneumonia as against 119, 142 deaths from broncho-pneumonia as against 103, and 207 deaths from pulmonary tuberculosis as against 188. Chronic organic heart and kidney diseases showed a slight increase in mortality.

Viewed from the point of age grouping, the mortality among infants under 5 years of age was considerably increased, due to an increase in the number of deaths from measles and from broncho-pneumonia, while the mortality of the old was considerably below that of the corresponding week of 1914.

The death rate for the first eighteen weeks of 1915 was 14.72 per one thousand of the population as against a rate of 15.63 during the corresponding period of 1914, a decrease of .91 of a point.

SEVENTH PAN-AMERICAN MEDICAL CONGRESS.—In the issue of the JOURNAL for April 8 we commented editorially on the coming seventh Pan-American Congress of Medicine, which is to meet at San Francisco during the week of June 17 to 21 inclusive, and on its convenient relation to the annual meeting of the American Medical Association the following week. In last week's issue of the JOURNAL we also noted the official plans for excursions from various points to San Francisco for the meeting of the American Medical Association. The transportation committee of the Pan-American Congress has also arranged a series of railroad excursions, particularly two special trains which will leave New York, one on Friday, June 11, for the Pan-American Medical Congress and one on Wednesday, June 16, for the meeting of the American Medical Association. These excursions are specially recommended to physicians who desire to attend one or both of these important medical meetings. For additional information and bookings, application may be made to Dr. H. L. E. Johnson, 1821 Jefferson Place, N.W., Washington, D. C.

DEDICATION OF THE BRADY INSTITUTE.—The new Brady Urological Institute, which was established and endowed at the Johns Hopkins Hos-

pital by Mr. James Buchanan Brady of New York City, was formally dedicated with appropriate exercises on May 4. Addresses were made by Mr. Brady, by Dr. Hugh H. Young, by Dr. Simon Flexner and by Dr. Edward L. Keyes of New York City. The Institute was established and equipped at a cost of over \$250,000.

DR. STRONG IN SERBIA.—Report from Washington on April 30 states that Dr. Richard P. Strong, head of the American Red Cross Commission sent to Serbia to check the epidemic of typhus, having arrived at Serbia and studied its conditions, reports that he believes it possible to control the epidemic in a short time if proper facilities are furnished. He asks that at least 175 more physicians, medical inspectors and fourth-year students be sent, and states that there is a great lack of hospital supplies of all kinds. The report further states that an international board of health has been established at Nish, with Prince Alexander of Serbia as president and Sir Ralph Paget of England as vice-president. It consists of the heads of Serbian, French and English sanitary commissions and representatives of the Serbian military and civil medical departments. It is intended to make Surgeon-General Gorgas director of this board, should he accept the offer of the Rockefeller Foundation to become a member of its force in Serbia. The remainder of the American commission, which numbered ten sanitarians and bacteriologists, have reached Salonica, Greece, and will join Dr. Strong at Nish shortly. They sailed from New York, April 4.

EUGENIC LEGISLATION A MISNOMER.—In the latest issue of the *Journal of Heredity*, Dr. W. C. Rucker, assistant surgeon-general of the United States Public Health Service and secretary of the American Genetic Association, has called timely attention to the difference between the principles of eugenics and so-called eugenic laws which have been advocated in many of our legislatures. He states that many of them do not deal with eugenics, but preventive medicine, as, for instance, those requiring a health certificate before marriage, and further says that, "Neither the science of eugenics nor public sentiment is ready for legislation putting further restrictions on marriage, so far as those restrictions are strictly eugenic rather than hygienic in intent."

REPORT OF BELGIAN RELIEF WORK.—Report states that the Commission for Relief in Belgium has sent to Rotterdam, for further distribution up to April 3, food and clothing to the value of \$49,174,519. The amount of food supplies necessary to keep the Belgian population alive is constantly increasing. The amount required for the present month is as follows: wheat, or its equivalent, 60,000 tons; rice, 10,000 tons; peas and beans, 5000 tons; bacon and lard, 1200 tons; preserved meat, 1200 tons; preserved fish, 1200 tons; condensed milk, 300 tons.

REPORT OF THE ROCKEFELLER FOUNDATION ON CONDITIONS IN SERBIA.—A report of conditions in Serbia made for the Rockefeller Foundation, which led to the appointment of Dr. Richard P. Strong of the Harvard Medical School as leader of a corps of physicians and sanitary engineers to begin relief work in that unfortunate country, states that on March 10 probably from 25,000 to 30,000 persons were suffering from typhus, and this, with other epidemics, was sweeping the nation. Cholera was expected with the advent of the warm weather and no preparations had been made to suppress it. Probably 300,000 persons were destitute. Exhausted by three successive wars, the country has nothing to give away to its own unfortunates. The Serbian peasant in normal times is isolated and self-sustaining. The country is economically and socially unevolved and unorganized to a degree unknown in America. The one railroad through the country is mainly occupied for military purposes and other roads are out of repair and almost impassable. The normal population of Nish, the temporary capital, has been increased from 25,000 to 80,000, due chiefly to the influx of refugees. School buildings and churches are crowded with the sick and dying. The report further states:—

"The conditions which have been described as existing at Nish (where the government is fully cognizant of the situation and where the members of the government themselves are not only in danger, but are undoubtedly aware of their danger) call for emergency measures, and indicate that it would be vain to try now to do anything beyond controlling the epidemic."

EUROPEAN WAR NOTES.—On May 3 Dr. Clapham King of the American Red Cross reached New York aboard the steamship *Patria*, on which he has returned with thirteen nurses from a tour of hospital duty in Serbia and France. All were members of the original units sent at the outbreak of the war. Eight of the twelve nurses and five of the six physicians constituting these units became infected with typhus fever, and two of the surgeons, Drs. Donnelly and Magruder, died of the disease. Dr. King and his companions have returned to this country for convalescence. The remaining four nurses and one surgeon have been removed from Gievglia, Serbia, to Belgrade.

On April 26 it was reported from London that the Prince of Wales National Relief Fund reached a total of £5,000,000. The sums raised in the several states of this country for the St. George's Relief Fund are as follows:—

Massachusetts	\$9,480.44
Pennsylvania	4,830.41
New Jersey	4,032.10
Connecticut	3,800.00
New York	3,173.57
Illinois	3,139.89

Pacific coast	2,146.92
Michigan	1,503.85
Ohio	1,286.87
Rhode Island	1,150.45

On May 8 the totals of the principal American relief funds for the European War reached the following amounts:—

	N. Y.	N. E.
Belgian Fund	\$1,029,913.23	\$255,620.83
American Ambulance	387,467.89	
Committee of Mercy	153,375.26	
Red Cross Fund		133,440.13
Prince of Wales	119,649.23	
Jewish Fund		61,572.22
Serbian Fund	52,137.31	26,968.25
Polish Fund		45,242.39
British Imperial		26,373.78
Belgian Red Cross		13,721.00

NEW YORK STATE HOSPITAL FOR THE CARE OF CRIPPLED AND DEFORMED CHILDREN.—The recently published report of the New York State Hospital for the Care of Crippled and Deformed Children for the year ending Sept. 30, 1914, shows that a total of 107 patients have been treated during the year; 22 were admitted with hip-joint disease, 18 with Pott's disease and 35 for various forms of infantile paralysis and its deformities. Thirty-two patients were discharged during the year, leaving 75 under treatment. 47.66% having tuberculous disease. Of the number discharged, 14 were cured and 18 improved.

DECLINE IN THE BRITISH BIRTH RATE.—In previous issues of the JOURNAL we have commented from time to time on the rapidly declining birth rate of France, and the slowly declining birth rate in Germany. A recent item in the *Manchester Guardian* calls attention to the decreasing birth rate of Great Britain and the serious effect upon it which may be expected from the present European War. Recently published statistics show that in 1913 the excess of births over deaths in Britain was 450,000, whereas in 1914 it was 438,000. From the latter figure, however, should be subtracted the 268,000 British emigrants who left the islands during that year, so that the total increase of population was only 170,000. It is obvious that the figures for 1915 will be seriously affected by the losses of the war. Indeed, it would appear that both in France and in Britain a rapid acceleration of the decline in population must ensue unless some unexpected form of racial regeneration should arise.

BOSTON AND NEW ENGLAND.

INDUSTRIAL ACCIDENT BOARD.—Walter P. Bowers, M.D., of Clinton, formerly president of the Massachusetts Medical Society, has been named as a member of the advisory committee

of the Massachusetts Industrial Accident Board. The membership of that committee is as follows: Dr. Frederic J. Cotton, Boston; Dr. F. W. Anthony, Haverhill; Dr. Samuel Fletcher, Chicopee; Dr. Samuel H. Calderwood, Roxbury; Dr. Francis D. Donoghue, Boston; Dr. Frank E. Allard, Boston, Dr. Wm. H. Ruddick, South Boston; Dr. Walter P. Bowers, Clinton. Since the committee was originally formed, Dr. Francis D. Donoghue has been selected by the board as its medical advisor, and is now serving in that capacity under salary.

REPORT OF THE WORCESTER CITY HOSPITAL.—The forty-fourth annual report of the trustees of the Worcester City Hospital publishes in thorough statistical arrangement the record of the work of that institution for the year ended Nov. 30, 1914.

“Five thousand, six hundred and fifteen (5615) bed patients were given 97,475 days’ treatment at an expense of \$158,005.82.

“Twenty-nine thousand, five hundred and forty-two (29,542) treatments were given in the out-patient department at an expense of \$8,579.60, or \$.29 per treatment.

“One thousand and seven (1007) were treated in the accident room at an expense of \$1,732.98, or \$1.721 per patient.

“There was a total of 97,475 days’ treatment in the hospital proper, 29,542 treatments in the out-patient department and 1007 treatments in the accident room at a total expenditure of \$170,820.40.

“The average expenditure for each bed occupied continuously throughout the year was \$591.67, as against \$577.89 in 1913. This does not include the expenses of the out-patient department, or of the accident room, nor does it include interest on investment or depreciation of plant.”

BOSTON VITAL STATISTICS.—The recently published report of the Boston Registry Department for the year 1914 shows that during the past year the births exceeded the deaths in this city by nearly 75%. The number of births recorded was 19,672, the number of deaths was 11,830, exclusive of 786 citizens of Boston who died in other cities. There were 8527 marriages of residents and 1687 of non-residents.

COLLECTION OF GUNSHOT WOUNDS FOR THE WARREN MUSEUM.—It is announced that Dr. Du Bouchet, surgeon-in-chief of the American Ambulance Hospital in Paris, has offered to present to the Warren Museum at the Harvard Medical School a collection of specimens obtained from operations and autopsies at the hospital during the war, illustrating the effect of modern projectiles on the tissues of the body. This collection, representing a wide variety of modern gunshot wounds, is expected to be the most complete in this country, with the exception of that

of the National Museum in Washington. In a recent letter from the American Ambulance Hospital, where he is at present serving with the Harvard Unit, Dr. Robert B. Greenough of Boston writes as follows of the character of the wounds there observed:—

“We are treating chiefly perforating gunshot wounds with compound fractures. Most of the wounds are infected when the bullet enters. The soil of the trenches is filled with all kinds of pathogenic organisms, including gas bacilli of several different strains. It is rare for any wound to heal by first intention. On the other hand, very severe infections are not numerous, and we have only three or four cases seriously ill today.”

REPORT OF THE MILK AND BABY HYGIENE ASSOCIATION.—The recently published report of the Milk and Baby Hygiene Association of Boston gives the following statistics: number of stations, 12; number of nurses, 14; number of well-baby clinics held, 665; attendance at clinics, 19,578; total number of babies cared for, 4097; number of deaths, 83; breast fed babies, 2249; partly breast fed, 818; artificially fed, 1030; visits made in the homes by the nurses, 50,275; average attendance at clinics, 29. The association has no endowment and is dependent upon voluntary contributions. In 1914 the work cost \$23,218 and during the present year \$30,000 will be required. That the work of this association is important and far-reaching cannot be questioned. It is to be hoped that funds will be forthcoming this present year to meet the expectations of the members of this worthy organization.

DRUG USERS IN INSANE HOSPITALS.—One of the inevitable results of the enactment of the Federal drug law has been in the crowding of hospitals with patients addicted to the use of drugs who, no longer able to obtain a supply of them, become mentally deranged and are committed to our state institutions. At Tewksbury there is an unusually large number of patients in whom deferred mental diseases developed when they were forced to give up the use of narcotics. The Norfolk State Hospital has a long waiting list of drug users. It is reported that proposals have been put forward for the establishment of a branch hospital at Springfield to take care of this increase. Many of the patients are anxious to escape from the dangers of their condition, but the majority are too firmly fixed in the habit to care for anything but its continuance. Report from Illinois states that since the enforcement of the drug law in that state went into effect, more than three hundred persons have been sent to insane hospitals, because they cannot get the drug they crave.

MEASLES IN WALTHAM.—Report from Waltham, Mass., on May 1, states that twenty-four cases of measles have recently been reported in

at city. Careful examination will be made of all pupils returning to school after vacation, to prevent a spread of the epidemic.

HOSPITAL BEQUESTS.—The will of the late Miss Helen Collamore of Boston, who died in this city on April 17, was filed in the Suffolk probate office on April 28. It contains numerous charitable bequests, including one of \$200,000 to the Massachusetts Homeopathic Hospital for the erection of a new building, to be known as the Collamore Building. A further sum of \$30,000 is also given to this hospital for the maintenance of three perpetual free beds. Bequests of \$5,000 each are made to the Children's Hospital, Boston Instructive District Nursing Association, to the Perkins Institution for the Blind, to the Industrial School for Crippled and Deformed Children, and to the Trustees of Boston University for the benefit of the Homeopathic School of Medicine of that university. The Massachusetts Homeopathic Hospital is also named as one of the residuary legatees.

FIRST CONFERENCE OF MASSACHUSETTS BOARDS OF HEALTH.—The first conference between the Massachusetts Association of Boards of Health and the State Department of Health was held in Boston on April 29. Seventy-five cities and towns of Massachusetts were represented. The speakers at the forenoon conference were Governor Walsh, Commissioner Allan J. McLaughlin, Dr. Charles W. Eliot, Professor Irving Fisher, Miss Ella P. Crandall, executive secretary of the National Organization of Public Health Nursing, and Professor William T. Sedgwick, president of the American Public Health Association.

Dr. McLaughlin spoke particularly of the desirability of better organization for health education, saying in part:—

"I believe that the time has arrived for a state-wide organization of all those interested in public health education. I believe that such an organization should include all health officers and every agency engaged in public health nursing or social service, or the teaching of hygiene in this Commonwealth. Organization is necessary to secure coöperation, to prevent duplication, and to get the full value of the efforts made, and the money expended for public health education."

The speakers of the afternoon, and their subjects, were: "The Control of Communicable Diseases," Dr. Eugene R. Kelley, State Department of Health; "The Relationship Between the State and Local Boards of Health," Dr. Lyman A. Jones, district health officer, Berkshire district; "The Health of the Farmer," Dr. John S. Hitchcock, district health officer, Connecticut Valley district; "The Vacation Health Problem," Dr. Adam S. MacKnight, district health officer, southeastern district; "The Continuing Problem of Vaccination," Dr. Samuel H. Dur-

gin, former chairman of the Boston Board of Health; "The Control of Cancer," Dr. Edward Reynolds, vice-president American Society for the Control of Cancer; "Some Problems of the Health Officer of a Small City," Dr. Francis G. Curtis, health officer, Newton; "Infant Mortality from the Standpoint of the State," Dr. William Hall Coon, district health officer, northeastern district.

Dr. Durgin, in his address on the continuing problem of vaccination, stated that the annual request made to the legislature to repeal the vaccination laws is made by a few citizens of the Commonwealth whose sincerity is unquestioned, but whose arguments, that vaccination produces other diseases in the person vaccinated, should be met with more scientific evidence. He, therefore, presented for the consideration of the association a resolution to this effect, which was adopted:—

"*Resolved*, That in the opinion of the Massachusetts Boards of Health, legislation should be secured by which all cases of supposed illness or injury caused by vaccination shall be forthwith reported to the state department and immediately investigated and recorded, and continued for a sufficient length of time to secure facts proving the truth or falsity of the charges."

DR. CREEL AS BOSTON HEALTH COMMISSIONER.—It was announced on May 3 that Dr. Richard H. Creel, of the United States Public Health Service, has accepted the offer of an appointment as health commissioner of the city of Boston and has received an indefinite leave of absence from Washington for this purpose. This appointment was made in accordance with the recent action of the Boston City Council, abolishing the present board of health and substituting therefor a health commissioner and a board of deputy commissioners. This reorganization was discussed editorially in the issue of the JOURNAL for Feb. 11. Probably an important element in determining Dr. Creel's decision to accept this post and the willingness of the Public Health Service that he should do so is the recent transfer of the Boston Quarantine Service from local to federal control. This transfer will officially take place on June 1 and on the same date Dr. Creel will come to Boston to assume his new duties. One of the first and most important of these will be the appointment of the deputy commissioners to have charge of the seven new divisions of the department. The ordinance passed by the city council provides that:—

"In appointing a deputy commissioner the health commissioner shall certify under oath that he is a person of recognized standing in his profession or occupation; that in the commissioner's opinion he is an expert in the work which will devolve upon him; that he is a person especially fitted by education, training or experience to perform the duties of the office, and

that the appointment is made solely in the interests of the city, such certificate to be filed with the city clerk and to be open for public inspection. The salaries of the deputy commissioners shall be fixed by the health commissioner, subject to the approval of the mayor."

Dr. Creel's acceptance of this important post is a matter for congratulation to the city of Boston, since his reputation in the public health service and the character of the work in which he has recently been engaged at New Orleans amply justify his reputation as an expert in matters of public health. From him is to be expected an efficient and constructive administration of the functions of the department of health, in a large city and seaport, without political fear or favor.

MASSACHUSETTS DENTAL SOCIETY.—The fifty-first annual meeting of the Massachusetts Dental Society was held in Boston on May 5, 6, and 7, under the presidency of Dr. Henry H. Piper of Somerville, who delivered his annual address at the afternoon session on May 5, followed by Dr. Eugene H. Smith. At the evening session on May 5 there was an address by Dr. Howard R. Raper of Indianapolis on "The Influence of Radiography on Dentistry." At the afternoon session on May 6, there were papers by Dr. William R. Pond of Rutland, Vt., and by Dr. Arthur H. Merritt of New York City; and at the evening session by Dr. Charles F. Painter of Boston, who spoke on "The Co-Relation of Advancement in Dental and Medical Education in Their Relation to the Public," and by Dr. Charles F. Ash of New York City. The morning session of May 7 was held at the Harvard Dental School, and at the final session that afternoon there was an address by Dr. Henry W. Gillett of New York City, followed by the installation of the following new officers:—

President, Dr. Charles M. Proctor, Boston; first vice-president, Dr. Frank T. Taylor, Boston; second vice-president, Dr. H. H. Cleaveland, Springfield; secretary, Dr. A. H. St. C. Chase, Boston; assistant secretary, Dr. Albert W. Day, Worcester; treasurer, Dr. Joseph T. Paul, Boston; editor, Dr. C. Edson Abbott, Franklin.

Massachusetts Medical Society.

ANNUAL MEETING.

THE annual meeting of the Massachusetts Medical Society, in observance of its 134th anniversary, will be held in Boston on Tuesday and Wednesday, June 8 and 9, 1915. All the exercises of the anniversary will be held at the Copley-Plaza Hotel, Copley Square, except the combined meeting of the sections on surgery on

Wednesday afternoon, which will be held at the Boston City Hospital.

A *Bureau of General Information* will be maintained by the committee of arrangements during Tuesday and Wednesday in the lobby of the Copley-Plaza Hotel, the headquarters of the society during the annual meeting.

The Annual Dinner and all General and Section Meetings (with the exception of the combined meeting of the Sections of Medicine and Surgery on Wednesday afternoon) will be held as in 1913 and 1914 at the Copley-Plaza Hotel. During both days of the meeting the facilities of the hotel will be at the disposal of the members of the society, and parking space for automobiles, with supervision, will be provided. By arrangement with the management, rooms may be secured at a reduced rate by fellows of the society desiring to spend Tuesday or Wednesday night in Boston.

Clinics and Demonstrations will be held at the various hospitals on Tuesday morning and will be related as far as possible to subjects to be discussed during the meeting.

The Boston Medical Library, 8 The Fenway, will be open for the inspection and use of the fellows during the days of the meetings.

The Harvard Medical School, 240 Longwood Avenue, and the Tufts College Medical School, 416 Huntington Avenue, will be open for inspection by the fellows both Tuesday and Wednesday.

A more detailed program of the exercises on each day of the meeting will be printed in the issue of the JOURNAL for June 3. The annual meeting of the council will be held at the Copley-Plaza Hotel on June 8.

DORCHESTER MEDICAL SOCIETY.

AT the annual meeting of the Dorchester Medical Society, held at the Hotel Brunswick on Apr. 21, 1915, the following officers were elected: President, J. T. Kendrick, M.D.; vice-president, W. E. Barnes, M.D.; secretary-treasurer, F. X. Corr, M.D.; advisory committee, M. T. Thurber, M.D., H. F. R. Watts, M.D., R. M. Merrick, M.D.

Obituary.

FRIEDRICH LOEFFLER, M.D.

DR. FRIEDRICH LOEFFLER, who died recently in Berlin, was born at Frankfort-on-the-Oder in 1852. He received his education at the Universities of Würzburg and Berlin and, as early as 1884, published the results of his first investiga-

ions on the bacillus of diphtheria. Klebs in 1883 had described a bacillus which he observed in diphtheritic membranes, but Loeffler was the first to cultivate the organism in artificial media and to reproduce the disease in animals by inoculation. He was thus able to obtain in guinea-pigs, rabbits, calves and pigeons a purulent conjunctivitis and tracheal lesions from which he recovered the organism in pure culture, thereby fulfilling Koch's laws and demonstrating the etiology of the disease.

In conjunction with his researches in diphtheria, Loeffler made a careful study of the use of aniline dyes in the staining of bacteria and became one of the great pioneers in bacteriologic method. The methylene blue stain which he devised is universally familiar to laboratory workers, and is particularly adapted to the demonstration of the metachromatic granules in diphtheria bacilli.

In 1888 Loeffler was appointed professor and director of the hygiene institute at the University of Greifswald and later was called to Berlin. In 1895 he became a member of the Imperial Institute and in conjunction with Koch and Haffky pursued important investigations relative to disinfection by means of steam. He also studied and differentiated the so-called red murrain of pigs, which thitherto had been confounded with swine fever.

In its obituary notice of him the *London Lancet* says that "Professor Loeffler as a pioneer will be placed among the foremost of German scientists. The results of his researches, both directly and indirectly, as leading up to the work of other observers (as, for instance, the introduction of the antitoxin treatment of diphtheria), have proved of the highest value to mankind, whilst the manner in which his investigations were conducted has formed a firm and constructive basis for other bacteriologists."

EMORY LINCOLN WHITE, M.D.

DR. EMORY LINCOLN WHITE died suddenly of heart disease at his home in Somerville, Mass., on April 29, 1915, aged 66 years.

He was born in Norton, May 15, 1848, and was educated in private schools and in the Harvard Medical School, from which he was graduated in 1872.

Dr. White joined the Massachusetts Medical Society in that year and settled in practice in Somerville, where he was prominent until his death. He was at one time a member of the Somerville Board of Health and also city physician; he was medical examiner for three life insurance companies and was a member of John Abbot Lodge of Masons. He is survived by his widow and one son.

Miscellany.

A STATE MEDICAL EXAMINATION IN THE SEVENTEENTH CENTURY.

THE following extract from Mr. John Fyvie's "Story of the Borgias" (p. 252) seems of interest as an account of a state medical examination three hundred years ago:—

"Ferrara, like Padua and Bologna, was celebrated for its school of medicine, but some notion of the qualifications of its practitioners may be obtained from the perusal of a medical diploma granted there as late as 1642, which the historian Citadella discovered in the archives of Ferrara, and which William Gilbert saw, engraved on parchment, in the library of that city. A certain Generoso Marini, wishing to practise as an authorized physician, applied to the judges for a diploma, and duly presented himself for their examination. What happened is thus set forth in the document itself, which is duly signed by 'Joannes Cajetanus Modoni, Index sapientium civitatis Ferrari,' and 'Franciscus Altramari, Cancellarius.'

"'Having publicly examined and approved the science and knowledge of medicine of Signor Generoso Marini, and his possession of the wonderful secret called Orvietano, which he exhibited on the stage built in the centre of the Piazza of this our city of Ferrara, in presence of its entire population (so remarkable for their civilization and learning) and in presence of many foreigners and other classes of people, we hereby certify that, in our presence also, as well as that of the city authorities, he took several living toads, not those of his own providing, which might have given suspicion of deception on his part, but from a great number of toads which had been caught in fields of the locality by persons who were strangers to him, and which were only handed to him at the moment of making the experiment. An officer of the court then selected from the number of toads collected five of the largest, which the said Generoso Marini placed on a bench before him, and, in presence of all the assembled spectators, he cut all the said toads in half with a large knife. Then, taking a drinking cup, he took in each hand one half of a dead toad and squeezed from it all the fluids and juices it contained into the cup; and the same he did with the remainder. After mixing the contents together he swallowed the whole; and then, placing the cup on the bench, he advanced to the edge of the stage, where for some minutes he remained stationary. Then he became pale as death, and his limbs trembled, and his body began to swell in a frightful manner, and all the spectators began to believe that he would never recover from the poison he had swallowed, and that his death was certain. Suddenly, taking from a jar by his side some of his celebrated Orvietano, he placed a portion of it in

his mouth and swallowed it. Instantly the effect of the wonderful medicine was to make him vomit the poison he had taken; and he stood before the spectators in the full enjoyment of his health. The Populace applauded him highly for the indisputable proof he had given of his great talent. And he then invited many of the most learned of those present to accompany him to his house, and he there showed them his dispensary, as well as his collection of many antidotes, and among them a powder made from little vipers, a powerful remedy in curing every sort of fever, as he had proved by different experiments he made on people of quality and virtue, all of whom he had cured of the fevers under which they were suffering. He also exhibited a wonderful balsam he had invented, which cured with great rapidity all bruises and wounds, as well as burns and scalds of every description. The said Generoso Marini had also great skill in drawing teeth, in which he exhibited an extraordinary dexterity. But that which most distinguished him was his wonderful power in restoring many persons to health who were suffering from divers incurable diseases. In consequence of the rare talent exhibited by Signor Generoso Marini, and as a proof of our love and respect for his wisdom, we have resolved by the authority placed in our hands publicly to reward him with our diploma, so that he may be universally recognized, applauded, and respected. In witness whereof we here set our hands and the public seal of the municipality of Ferrara.'"

SANITARY IMPROVEMENT IN OYSTERS.

ON May 2 the United States Department of Agriculture issued the following statement relative to recent improvement in the sanitation of oysters:—

"Oysters now being shipped from northern oyster beds in interstate commerce are safer than ever before, being as safe a food as milk. This condition has been brought about through the sanitary surveys of oyster beds conducted co-operatively by the Public Health Service and the Department of Agriculture, by the hearty co-operation of the state shellfish authorities with the federal authorities, and finally by a realization on the part of the oyster men that they themselves in the interests of their industry must prevent the taking of oysters from suspected or polluted beds.

"As a result of the survey of oyster beds by the Federal authorities, in coöperation with state authorities, every oyster bed polluted by sewage or other causes, from Virginia to Massa-

chusetts, the northern oyster-producing region, has been closed and many beds placed under such restrictions as to the taking and handling of oysters as to make it practically impossible for oysters at all subject to pollution to be taken and shipped. All the oyster beds in the states mentioned have been so charted that when certain beds are closed, owing to pollution or other causes, it is easy to establish from these maps the definite area covered by these beds.

"In certain cases these restrictions have compelled the transplanting of oysters for a time long enough to make them absolutely free from any danger of pollution, or have limited the taking of oysters to the seasons when the beds are in absolutely clean condition. In this work all the states concerned have coöperated most actively and, what is regarded as of great importance by the federal authorities, the oyster men themselves are seeing to it that no oysters from the prohibited sources enter the local markets or are shipped inland."

MEMORIAL RESOLUTIONS.

HENRY CUTLER BALDWIN, M.D.

At a meeting of the Boston Society of Psychiatry and Neurology, held April 15, 1915, the following memorial was read:—

Dr. Henry Cutler Baldwin died very suddenly on the afternoon of February 28, 1915. He had engaged in his professional work on the morning of that day, and his death was most unexpected and a shock to his family and many friends, although it would seem that he himself must have recognized symptoms of danger for nearly two years.

Dr. Baldwin, the son of Rollin Mallory and Maria Louise (Colton) Baldwin, was born in Boston, October 27, 1859. He was graduated from Harvard College in 1880, and from the Harvard Medical School in 1884. He was a surgical house pupil in the Massachusetts General Hospital in 1883-1885, and after his hospital service received an appointment as assistant physician of the McLean Hospital, which position he held for nearly a year, resigning in December, 1885, to become private physician to a gentleman in a tour around the world, which was broadening in its influence and furnished many pleasant memories in after-life. Immediately after his return he again went abroad for medical study, and in the fall of 1887 began in Boston the practice of medicine, in which he was eminently successful. In college and in the professional school he took high rank and gave promise of the success he in later life attained

in his hospital work, both as a pupil and a physician, he was faithful, thorough, painstaking, and spared no time or strength in doing his full duty.

From his service in the Massachusetts General Hospital one might have predicted for him the career of a surgeon, and to this he was early inclined, but his experience at the McLean Hospital and his appointment as assistant in neurology in the out-patient department of the Massachusetts General Hospital turned him to the field of neurology and psychiatry, in which his practice chiefly lay. He was exceedingly successful in the treatment of difficult cases of long duration that required infinite patience, persistence and ingenuity in a process of reeducation. He was a forceful, self-reliant man and had great executive ability, which enabled him to manage extremely difficult cases. He was firmly convinced that the physician should be in control and declined the care of those who would not follow directions. He gained the confidence of his patients by absolute devotion to them, never hesitating to do anything that promised for their advantage, even though the service might seem to be more within the province of the nurse than the physician. He was always ready by night and day, and for a long time it seemed that he had the physique to meet all demands upon him. As an expert witness, in which capacity he frequently served, he showed the same thorough and painstaking preparation that was manifested in all his work.

He was a member of many medical societies, but took especial interest in the Boston Society of Psychiatry and Neurology, of which he was secretary from 1898 to 1904, and president in 1909. He often made brief communications and showed cases, but rarely read a formal paper. As chairman of the board of trustees he formulated a plan for the development of the Boston Insane Hospital, of which he officially saw only the beginning, but which has since been more fully realized. This plan was presented by him in a paper read in January, 1900, before the Boston Society for Medical Improvement.

A man of rare personal qualities, exceptional professional ability, absolute common sense, forcefulness and tenacity of purpose, he leaves a place in the community which it will be difficult to fill.

Resolved, That the Boston Society of Psychiatry and Neurology place on record its appreciation of the character and attainments of Dr. Baldwin and the deep sense of the loss it has sustained in his death.

Resolved, That a copy of these resolutions be sent to Mrs. Baldwin and his brother, be spread on the records of the Society, and printed in the BOSTON MEDICAL AND SURGICAL JOURNAL.

PHILIP COOMBS KNAPP, M.D.,
GEORGE T. TUTTLE, M.D.

Correspondence.

THE HARVARD UNIT AT THE AMERICAN AMBULANCE IN PARIS.

AMERICAN AMBULANCE HOSPITAL.

NEUILLY, PARIS, FRANCE, April 19, 1915.

Mr. Editor: The Harvard Unit assumed its responsibilities at the American Ambulance on April 1. There are four surgical services in the hospital, one in charge of Dr. C. W. Du Bonchet, surgeon-in-chief, one in charge of Dr. Joseph A. Blake, a third in charge of Dr. Mignot, and the fourth or so-called University Service, administered by the Harvard Unit, during April, May and June, with Dr. Harvey Cushing the ranking member in charge of the neurological cases, and Dr. R. B. Greenough the active chief surgeon.

There are also special departments, eye, nose, throat and ear, x-ray, dental, massage, and a genito-urinary department in process of organization.

The hospital is housed in the large Lycée Pasteur recently built and never used before; it was taken over by the Government and assigned to the American Ambulance. It has been skilfully adapted to its new use and serves its purpose admirably. The building has three main floors divided into wards arranged about a central court and a wing devoted to offices, supply rooms and the special departments. On the top floor of this wing are the very adequately appointed operating room, sterilizing room, laboratory and office of the Harvard Unit.

The hospital contains about 500 beds with a possible increase beyond this number. The University Service has charge of 168 of these beds, practically the entire third floor of the building.

Everyone connected with the hospital has shown the greatest courtesy to the Unit and its needs have been supplied in a most cordial spirit of co-operation and in a most generous manner. For the first two weeks the service was comparatively light which enabled the chiefs to organize the work and establish an adequate record system. The two residents and the three house officers were thus able to make a careful study of the cases. Each house officer has charge of six wards of nine or ten beds each and both residents and house officers live at the hospital. Two stenographers, speaking both French and English, and half the time of a photographer, are at the disposal of the Unit.

An idea of the activity of the service may be gained from the fact that during the first two weeks the Harvard Unit discharged 51 old and admitted 65 new patients, the largest number received on any one day being 23. The cases are sent to well-equipped convalescent homes as soon as their condition will allow. This provision makes possible a constantly active service, almost as active in fact as that of any of the large general hospitals in Boston.

Even the very fresh wounds, of which the hospital is now receiving many, are most of them septic; some of them seriously so. There have been several cases of infection with gas-producing anaerobic bacteria but none of them have demanded radical surgery. We have known of no cases of tetanus occurring in the hospital which may well be attributed to the routine prophylactic doses of anti-tetanic serum given at the front.

The operations on the infected cases have consisted in the establishment of proper drainage and the removal of foreign bodies and bone fragments. A musculo-spiral nerve dissection and freeing, and a facial nerve suture in the canal by Dr. Cushing, a plastic of the face by Dr. Greenough, and a transfusion on Dr. Blake's service by Dr. Vincent have been examples of clean surgery. There have been a surprisingly large number of peripheral nerve lesions and several interesting cranial injuries. Many of the

cases have also needed orthopaedic treatment in the way of apparatus, to correct deformity and retain proper alignment in fractures. A very large number of compound comminuted and infected fractures of the long bones present special problems.

Dr. Strong's departure for Serbia has robbed the Unit of one of its most important members. He was able to plan the bacteriological and laboratory lines of investigation and these lines are being closely followed by Dr. Rogers and Dr. Benet.

The service bids fair to be a most interesting and valuable one and the hospital seems to welcome the assistance of these groups of American surgeons.

Very truly yours,

ROBERT B. OSGOOD, M.D.

CORSETS, PTOSIS, AND SACROILIAC STRAIN.

ALLSTON, MASS., May 1, 1915.

Mr. Editor: I have read with much interest the contribution of Dr. R. M. Green in your number of April 22, on the relation of ptosis and sacroiliac strain to pelvic conditions, and the value of proper corseting in their treatment. The article is certainly to be commended for calling attention to a most important, yet greatly neglected, subject. On the basis of experience with similar cases, as seen in adult orthopedic clinics, I cannot, however, wholly agree with some of the ideas expressed.

In the first place, the division of all corsets into two groups, those which lace in front and those which lace behind,* as representing good and bad types, respectively, does not seem to me to be a pertinent classification, nor can I agree that the lace-back corsets "are all bad." The fundamental difference does not lie in the position of the lacing, but in what the corset accomplishes. Certainly it is just as true that there are lace-front corsets which are bad as it is true that lace-back corsets may be found which are to be recommended. It is my belief that many, if not the majority of, orthopedic surgeons in Boston are today using lace-back corsets.

The requisites of a good corset do not depend so much on its style as on its function. From this viewpoint a good corset is one which, granted it is of suitable size, has a snug-fitting bottom, with a loose top and sides, and a relatively straight, firm back, furnishing a definite lifting power and assisting in the correction of faulty posture. It should be so constructed, moreover, that it may be readily altered, as practically no ready-made corset is wholly good without a few careful alterations.

A corset which meets these requirements will not only support the viscera, but do this without cramping, for it is just as important that ample space be allowed in the upper part of the corset for the accommodation of the lax abdominal wall, as it is that the corset should be tight below to elevate and support this laxity. In other words, the corset must be designed to transfer the superfluous flesh and the sagging abdominal contents from below to above, rather than to squeeze them directly backward against the spine. The lace-back corset will do this as well as the face-front, if it is properly fitted at the bottom, darts being taken in the lower edge when necessary. While the application of a corset in recumbency is ideal, and, in fact, is the best way for a lace-front corset to be applied, this method is not always practicable, and can be avoided with a lace-back type. With the latter, the patient, standing, buckles on the unlaced corset, pulls it well down, and then lifts the abdomen inside with one hand, while the

*It should be noted that in the article in question the exact phrase is "those that lace *only* behind." This seems intended to convey a somewhat different idea from that assumed by our correspondent.—EDITOR.]

other tightens the bottom or pelvic lacing, so holding the position gained.

It is my experience, however (in this the orthopedist may of course differ from the gynecologist), to observe very few cases of visceroptosis in which all the symptoms could be accounted for by this condition *per se*, or in which, indeed, the ptosis did not appear to be but a contributory factor. To one familiar with the statics of the human body, it does not seem probable for a visceroptosis of any degree to exist without materially interfering with posture, and being productive of the muscle strain attendant to improper balance. Careful examination of patients with ptosis usually reveals other postural defects, notably an increased lordosis of the lumbar spine, which is either the primary defect, or is secondarily produced by an attempt on the part of the individual to alleviate the strain on the muscles of the back, which has been caused by the added anterior weight of the pendulous abdomen. It is this strain of the muscles and ligaments of the low lumbar region from faulty posture, often attended by arthritic changes from long continued irritation, which is responsible for a large measure of the discomfort and referred pain in these cases. The relief of the condition depends fully as much, then, on resting the muscles and ligaments of the low back, and in supporting and straightening the lumbar spine, as in elevating the abdomen. Any corset which will relieve the ptosis necessarily shifts the center of gravity of the body toward the spine, and so relieves the back strain, but the necessity of having, in addition, a straight firm support, against which the lumbar spine may be drawn and held, is obvious.

In regard to flat-foot and sacroiliac strain, as mentioned in this connection in Dr. Green's article, while both are productive of backache, and may, of course, accompany visceroptosis, the static results of the former should be considered a distinct entity, while the latter is rarely seen in pure faulty posture, the strain and pain in these cases being largely muscular, and located in the lumbo-sacral region.

Methods of treatment necessarily vary with the experience of different men, and equally good results are often obtained by quite dissimilar procedures. It is rather in defence of the ideas expressed above, than in criticism of those of the article under discussion, that the undersigned has taken the liberty of submitting these remarks.

Very truly yours,

EBEN W. FISKE, M.D.

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING MAY 1, 1915.

CONTRIBUTIONS.

Dr. N. B. Murphy, Bangor, Mich.....	\$ 25.00

Total receipts.....\$6585.5

Disbursements for the week ending May 1:
35 standard boxes of food @ \$2.30..\$ 80.50

Previously reported disbursements:

1625 standard boxes of food @ \$2.20.. 3575.00
 1274 standard boxes of food @ \$2.30.. 2930.20

Total disbursements.....\$6585.70

Deficit \$0.20

F. F. SIMPSON, M.D., *Treasurer*,
 7048 Jenkins Arcade Bldg.,
 Pittsburg, Pa.

Dr. J. Riddle Goffe, of New York, says that in a letter just received from Dr. Jacobs, of Brussels, the latter summarizes the situation of our Belgian Colleagues as follows:

1. Many doctors were killed, consequently the widows and orphans deprived of everything, are without a home, without means, with nothing left.

2. All country doctors or those living in small towns are ruined by loss of every possession they had.

3. Doctors in large cities are ruined by commandeering and war-taxes.

4. The largest part of the Belgian population has become the prey of infectious diseases, epidemics, with a large infant mortality.

5. Ruined civilian populations cannot pay for medical advice, consequently several physicians are compelled to work for nothing, others are obliged to undertake any labor for gain as a means of livelihood, with results that are terrible for the population.

The opportunity is here created for the medical profession of the world to show the brotherly feeling which exists among them, and they can do this by helping us with the necessary funds.

UNITED STATES CIVIL SERVICE EXAMINATION.

JUNE 8, 1915.

The United States Civil Service Commission announces an open competitive examination for physiologist, for men only. From the register of eligibles resulting from the examination certification will be made to fill a vacancy in this position in the Dairy Division, Bureau of Animal Industry, Department of Agriculture, Washington, D. C., at a salary ranging from \$2500 to \$3000 a year, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

The duties of this position will be to take charge of investigations in the secretion of milk and will involve a general fundamental study of the factors controlling the secretion of milk.

An M.D. degree or a Ph.D. degree in physiological work, and at least four years' subsequent experience in the investigation of physiological problems, are prerequisites for consideration for this position.

Applicants must not have reached their fiftieth birthday on the date of the examination. Under an act of Congress applicants for this position must have been actually domiciled in the State or Territory in which they reside for at least one year previous to the date of the examination. A ten-cent internal revenue stamp must be attached to the county officer's certificate in Form 304. This examination is open to all men who are citizens of the United States and who meet the requirements.

Persons who meet the requirements and desire this examination should at once apply for Forms 304 and 095, stating the title of the examination for which the forms are desired, to the United States Civil Service Commission, Washington, D. C.; the Secretary of the United States Civil Service Board, Post Office,

Boston, Mass.; Philadelphia, Pa.; Atlanta, Ga.; Cincinnati, Ohio; Chicago, Ill.; St. Paul, Minn.; Seattle, Wash.; San Francisco, Cal.; Customhouse, New York, N. Y.; New Orleans, La.; Honolulu, Hawaii; Old Customhouse, St. Louis, Mo.; or to the Chairman of the Porto Rican Civil Service Commission, San Juan, P. R. Applications should be properly executed, excluding the medical certificate, and must be filed with the Commission at Washington, with the material required, prior to the hour of closing business on June 8, 1915.

EXAMINATION OF CANDIDATES FOR ASSISTANT SURGEON.

UNITED STATES PUBLIC HEALTH SERVICE.

Boards of commissioned medical officers will be convened to meet at the Bureau of Public Health Service, 3 "B" Street, S.E., Washington, D. C., and at the Marine Hospitals of Boston, Mass.; New York, N. Y.; Chicago, Ill.; St. Louis, Mo.; Louisville, Ky.; New Orleans, La.; and San Francisco, Cal., on Monday, June 21, 1915, at 10 o'clock A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service, when applications for examination at these stations are received in the Bureau.

Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and must furnish testimonials from two responsible persons as to their professional and moral character. Service in hospitals for the insane or experience in the detection of mental diseases will be considered and credit given in the examination. Candidates must have had one year's hospital experience or two years' professional work. Candidates must be not less than 5 feet, 1 inches, nor more than 6 feet, 2 inches, in height, with relatively corresponding weights.

In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate and that they will serve wherever assigned to duty.

The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists of examination in the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order. They will receive early appointments. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon.

Assistant surgeons receive \$2000, passed assistant surgeons \$2400, surgeons \$3000, senior surgeons \$3500, and assistant surgeon generals \$4000 a year. When quarters are not provided, commutation at the rate of \$30, \$40, and \$50 a month, according to the grade, is allowed. All grades receive longevity pay, 10 per cent. in addition to the regular salary for every five years up to 40 per cent. after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses.

For invitation to appear before the board of examiners, address "Surgeon-General, Public Health Service, Washington, D. C."

UNITED STATES NAVY MEDICAL CORPS.

The surgeon general of the United States Navy has recently issued a revised circular for the information

of persons desiring to enter the navy medical corps, from which the following data seem of special importance:

A candidate for appointment in the medical corps of the Navy must be a citizen of the United States, between 21 and 30 years of age, a graduate of a reputable school of medicine, and must apply for permission to appear before a board of medical examiners. The application *must be in the handwriting of the applicant*, and must be accompanied by the following certificates:

(a) Letters or certificates from *two* or more persons of good repute, testifying from personal knowledge to good habits and moral character.

(b) A certificate to the effect that the applicant is a citizen of the United States.

(c) Certificate of preliminary education: The candidate must submit a certificate of graduation from an accepted high school or an acceptable equivalent.

(d) Certificate of medical education: This certificate should give the name of the school and the date of graduation.

(e) If the candidate has had hospital service or special educational or professional advantages, certificates to this effect, signed by the proper authorities, should also be forwarded.

The applicant will save unnecessary correspondence if he will make sure when submitting his application that the qualifications enumerated above are clearly and plainly described in his letters or certificates.

The next examination of candidates will take place on or about July 6, 1915, at the following naval stations: Washington, D. C.; Boston, Mass.; New York, N. Y.; Philadelphia, Pa.; Norfolk, Va.; Charleston, S. C.; Great Lakes, Ill.; Mare Island, Cal.; Puget Sound, Wash. Applications accompanied by the necessary letters or certificates should reach the Bureau of Medicine and Surgery, United States Navy Department, Washington, D. C., not later than June 26, 1915.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE WEEK ENDING APRIL 24, 1915.

April 13, Medical Director E. H. Green, placed on the retired list from April 18, 1915, detached, all duty; to home.

Asst. Surgeon Talmadge Wilson, M.R.C., detached, Naval Medical School, to Asiatic Station, via May Transport.

Asst. Surgeon S. M. Taylor, M.R.C., detached, Naval Medical School, to Asiatic Station, via May Transport.

April 21, P. A. Surgeon Micajah Boland, detached, *Iris*, to home.

P. A. Surgeon J. C. Parham, to Navy Yard, Charleston, S. C.

Asst. Surgeon H. M. Stenhouse, M.R.C., detached, Naval Medical School, Washington, D. C., to *Iris*.

April 23, Surgeon A. D. McLean, Commissioned from June 25, 1915.

Surgeon W. S. Pugh, commissioned from June 25, 1915.

Surgeon C. E. Ryder, commissioned from December 15, 1915.

Asst. Surgeon C. A. Costello, M.R.C., detached, Navy Recruiting Station, Chicago, Ill.

April 22, the following Assistant Surgeons have been detached from the Naval Medical School, Washington, D. C.:

Medical Reserve Corps. William McKinney, E. L. Matthews, J. F. Newberger, W. E. Lawhead, A. L. Bass, Arthur Freeman, A. R. Barrow, J. M. Quinn, J. H. Harris, C. F. Glenn, A. C. Thompson, G. E. Faulkner, N. M. McClelland, R. L. Natkemper, A. E. Mann.

NOTICE.

DINNER TO DR. THEOBALD SMITH. The postponed dinner to Dr. Theobald Smith is to be held at the Harvard Club, Boston, on the evening of Wednesday, June 2. Those wishing further information about the dinner may apply to

DR. MARSHAL FABYAN,
379 Commonwealth Avenue, Boston.

SOCIETY NOTICES.

ESSEX SOUTH DISTRICT MEDICAL SOCIETY.—The annual meeting of the Essex South Medical Society will be held Thursday, May 13, 6.30 P.M., at the Relay House, Nahant. Election of officers for 1915-1916 will follow the dinner.

The meeting will be held jointly with the Lynn Medical Fraternity.

Dr. H. D. Arnold, Dean of the Harvard Post-Graduate Medical School, will be a guest and will talk on "Circulatory Disorders."

The censors meet Thursday afternoon, May 13, 2 P.M., at Salem Hospital, for the examination of candidates for admission to the Society.

J. F. O'SHEA, M.D., *President*,
H. P. BENNETT, M.D., *Secretary*.

HARVARD MEDICAL ALUMNI ASSOCIATION.—The triennial meeting of the Harvard Medical Alumni Association will be held in Boston on May 20. Morning program, at the Massachusetts General Hospital, Boston City Hospital, Free Hospital for Women, and Psychopathic Hospital.

1 P.M., lunch at the Harvard Medical School. Afternoon program, at the Peter Bent Brigham Hospital, The Children's Hospital, The Cancer Hospital, and all the departments in the buildings of the Harvard Medical School.

Dinner at the Harvard Club at 7.30 P.M. All Alumni whether or no members of the Association, are invited.

CHANNING FROTHINGHAM, JR., M.D.,
Chairman of Committee of Arrangements.

RECENT DEATHS.

DR. WILLIAM B. RICE, who died on May 2 at Buffalo, N. Y., was born at Port Byron, N. Y., in 1826. After teaching school for a time he studied medicine and subsequently practised his profession for many years in Niagara County. He was particularly known for his effective work during an epidemic of enteric fever at Niagara Falls. He is survived by three daughters and two sons.

DR. W. P. DILLON of Ottawa, Canada, is reported to have been killed in action with his regiment in France. He had been for many years a well-known local practitioner at Ottawa.

DR. ARCHIBALD ELEXIS MACDONALD, formerly a practitioner in the North End of Boston, died at Jamaica Plain, Mass., April 27, aged 87 years. He was born in Prince Edward Island. He graduated from the Harvard Medical School in 1865 and joined The Massachusetts Medical Society in the same year, being a Fellow at the time of his death. He was at one time surgeon of the Ninth Regiment, M.V.M., and a member of the Ancient and Honorable Artillery Company. One of his sons is Dr. Charles F. MacDonald of Boston, and he is survived by two daughters and two other sons.

Address

"DO'S" AND "DON'TS" IN THE DIAGNOSIS OF EARLY PULMONARY TUBERCULOSIS IN ADULTS AND CHILDREN."*

By JOHN B. HAWES, 2d, M.D., BOSTON.

THERE is no more important subject in medicine than the early diagnosis of tuberculosis. It is one concerning which I frankly admit that I can offer nothing especially new. I can merely call attention to various well-known points, and reiterate the same old truths, the majority of which every doctor is, or should be, familiar with. I am purposely arranging what I have to say in very elementary form. The medical literature of today is so filled with articles of complex nature, detailed, and often difficult to understand and digest, that I believe one which is simple in the extreme may be a relief, and may be welcomed by the general practitioner.

Despite the great number of papers and books which have been written on the diagnosis of early tuberculosis, the medical profession has still a long way to go. I am constantly receiving application blanks for admission to our state sanatoria, in which the doctor has classified his patient as "incipient," and yet has frankly given certain data in the way of temperature, pulse, loss of weight, etc., which directly contradict his statement. This, al-

though not satisfactory, at least means that the physician is frank and honest, and has given the facts as he saw them.

On the other hand, I am constantly sending patients to our State Sanatorium at Rutland,—reserved, as you know, for early and incipient cases,—because from everything that I could judge by on the application blank, the patient was really a Rutland case. Far too many of these patients on their arrival at the Sanatorium are at once classified as "advanced." On the whole, however, the situation is slowly improving. In 1910, when the state board, of which I am secretary, first took over the Rutland Sanatorium, doing away with the old system of special examiners for that institution, and placing this work on the shoulders of the medical profession of this state, where it really belonged, the percentage of incipient cases at Rutland fell from about 30%, under the old system, down as low as 18% of the whole number. Gradually the proportion of incipient cases has been rising, so that during the past year the proportion of incipient cases was 37% of the whole,—the highest that it has ever been in the history of the Rutland State Sanatorium.

I have taken up what I consider the most important points, and have discussed each one in turn.

DIAGNOSIS IN ADULTS: "DO'S."

Remember the following points:—

- (1) Take a careful history of your patient.

This procedure is probably more neglected

* Read at a meeting of the South Boston Medical Society, Feb. 8, 1915.

than any other. The average busy physician with an office full of patients, or with various outside visits to make, does not like to listen to the long and often disconnected tale of a worried and nervous patient. He wants to get down to bed-rock, as he calls it, at once,—to get at the real facts, which he believes he will find by examining the chest. He makes a great mistake in so doing. History taking is an art in itself, and one well worth cultivating. The time which it takes need not be long. While it is well in some cases to let the patient do most of the talking, in most instances it is better for the physician to ask certain definite questions in a logical and regular sequence. I have a definite routine in my own work, from which I very seldom vary. It takes but a few minutes to find out concerning family history. If there is a family history of tuberculosis, it is important to go further and to find out concerning the intimacy and length of contact with the afflicted person. The habits of the patient should be briefly gone into, especially the question of syphilis.

In the past history, the children's diseases are of comparatively minor importance, except measles,—particularly if this occurs in adult life. I invariably ask every patient whether during the years from 15 to 21 he considered himself, or was considered by his parents, as of the strong and robust type, the thin and wiry type, or of the delicate type. The correct answer to this will give much valuable information.

Coming to the present illness, it is important to ask not, "When did you first feel sick?" but rather, "When did you last feel perfectly well?" This should be followed by finding out exactly for what special thing the patient comes for advice. It takes far longer to describe this process than it does to take the history itself, in most cases.

(2) *Remember the paramount importance of constitutional signs and symptoms.*

If in diagnosing a given case of suspected tuberculosis, I were obliged to give up one of two things,—either the use of my stethoscope and percussion, or a careful inquiry into the constitutional signs and symptoms of the patient, I would decide at once to do away with auscultation and percussion, as of infinitely less importance. In far too many cases the physician pictures in his own mind a case of tuberculosis as a patient with a bad cough and a positive sputum, and on examination, with dullness, bronchial breathing, and râles at one or both apices. In most cases, except for a cough, which is usually present, the constitutional signs and symptoms are far more striking, and their study gives far more information than anything else.

(3) *Remember that loss of weight must be satisfactorily explained.*

Among my routine questions I ask every pa-

tient: First, "What is your maximum weight?" Second, "Your present weight?" Third, "What do you consider good average weight for you in health?" Fourth, if the patient has lost weight, "Over how long a period has this loss taken place, and how do you account for it?"

Unless these questions are asked, and the matter gone into in detail, the physician is apt to be led astray. A patient might say that he has lost twenty pounds in weight during the past six months; unless this loss can be satisfactorily explained, it would be a very important factor indeed. On inquiry, however, it might be found, and frequently is found, that there is a perfectly good reason for this decline. Unless this loss can be explained in some way, it should be considered as an important factor in your final diagnosis.

(4) *Loss of strength and energy.*

Along with loss of weight, there may or may not be a loss of strength and energy. The combination of the two is of more importance than either one alone. This is something concerning which inquiry should be made in every case.

(5) *Do not forget the importance of undue fatigue and ease of tire.*

I always ask my patients if they feel rested in the morning after a good night's sleep. I likewise inquire as to whether they are more tired out at night than they feel that they ought to be. Most of us after a hard day's work are naturally tired in the evening. There is, as of course you know, a vast difference between wholesome physical fatigue, which is a natural and proper feeling, and that other kind of fatigue, which is distinctly abnormal. I find that generally patients have very shrewd ideas on this subject. It is important to bear in mind, particularly in women, that in neurasthenic conditions and others of a similar nature, this symptom of undue fatigue and ease of tire may be a prominent one.

(6) *Continual or occasional evening fever must be explained.*

The patient's own ideas as to whether or not he or she has had fever are apt to be very vague. This is a point which the physician must investigate for himself. The thermometer is not used anyway nearly as much as it should be. In the absence of other definite causes, if a patient is found to be running an afternoon or evening fever of 99° or over, a tentative diagnosis of some such infection or toxemia as tuberculosis is justifiable. It is not always possible, and often is impossible, to get satisfactory results with temperature and pulse records at home. In many instances, however, one can obtain valuable information in this way.

(7) *Remember the importance of a subnormal temperature accompanied by a high pulse.*

In a recent valuable article, Dr. Arthur K. Stone of this city has emphasized this point. It

is one rarely mentioned in the literature. I do not say that the combination of the subnormal temperature and high pulse always means tuberculosis. I do say, however, that this combination, along with other signs and symptoms, may be and often is caused by tuberculosis.

(8) *Remember that a hemorrhage is evidence of pulmonary tuberculosis until the contrary is proved.*

There ought to be very little discussion needed on this point. I believe that every physician knows this just as well as I do, but the fact remains that doctors throughout the length and breadth of this Commonwealth are continually telling patients who have consulted them for a hemorrhage of this kind that the blood comes from the nose, the throat, the gums or the stomach. In other words, they are afraid to tell the patient the truth about the matter, simply because in other respects he often seems so perfectly well and strong.

Of 80 patients who had been treated in our state sanatoria, and who first consulted a doctor on account of a hemorrhage, 39 were told by their physician that they did not have consumption, and that the blood did not come from the lungs. Failure to observe this rule is causing many tragedies and unnecessary deaths.

(9) *Bear in mind that pulmonary syphilis is not so uncommon as it is supposed to be.*

If you bear this fact in mind, you will once in a while make a brilliant cure of a well-marked case of tuberculosis by means of mercury and iodide of potash. Particularly in those cases in which the lung signs are unusual and obscure, if you can obtain a definite history or even an indefinite history of luetic infection, give the patient the benefit of the doubt, have a Wassermann done, or even without the Wassermann, give him mercury and iodide of potash.

(10) *Remember that early cases of exophthalmic goitre may simulate early pulmonary tuberculosis in every way.*

While the treatment of these two conditions is exactly the same, it is, of course, quite unfair to condemn a patient as a consumptive when he is really suffering from excessive thyroid secretion. In women where the nervous symptoms predominate, although the thyroid enlargement may be of the slightest, and ocular signs may be absent, remember and at least consider the question of hyperthyroidism before you state definitely that the patient has consumption.

(11) *Depend more on your thermometer, your history and constitutional signs and symptoms than you do on percussion and auscultation.*

As I have stated before, physicians are far too prone to jump for the stethoscope and to look for something which they can see, feel or hear, instead of studying the somewhat less tangible

and less satisfactory, although far more important, evidence obtained from the patient's history, habits and symptoms.

(12) *Remember to use your common sense.*

Bear in mind that it is a human being, and not merely a pair of lungs, that you are dealing with. If medicine were an exact science and if our methods of diagnosis were those of mathematical precision, this point would not be so important. In my mind, the art of medicine should play just as great a part as the science of medicine. One will not go so far in diagnosing tuberculosis, or any other disease, in its early stages, therefore, unless he considers the human side of the subject.

"DON'TS."

Do not forget the following:—

(1) *Don't be in too much of a hurry.*

Some diagnoses can be hurried. It takes only a few minutes to take a drop of blood and to stain and examine a slide for malaria. It often takes no time at all to diagnose a broken arm or leg. One cannot hurry the diagnosis of early tuberculosis, however.

(2) *Don't forget to strip the patient to the waist.*

Whether man or woman, child or adult, this should be done in every case. No question of false modesty should be allowed to stand in the way of so doing. The physician who attempts to listen through the clothing at once classifies himself as a remarkably poor doctor.

(3) *Do not expect to find marked signs in the lungs in every case.*

If you will remember the pathology of early tuberculosis, you will, of course, see how impossible it is for very marked signs to be present. As I stated before, the old picture in most of our minds of incipient tuberculosis consisted of dullness, bronchial breathing, and râles at one apex. This combination does not mean incipient tuberculosis. The students at our medical schools do not receive sufficient training on this matter, for the evident reason that cases of early tuberculosis are hard to demonstrate.

(4) *Do not wait for a positive sputum.*

How many patients there are who have been lulled into a sense of false security by the possession of a postal card from a local or state board of health, bearing the words, "Tubercle bacilli not found." While the statement that "When bacilli are present in the sputum, the patient is already in the advanced stages, and his chances of cure nearly gone," may be an extreme one,—fundamentally it is true. Therefore, if there are other signs and symptoms, showing that your patient is sick, even if the sputum may be negative, give your patient a chance, and start him on the right track. It may be

wise to explain the situation to him frankly, and to say that while you cannot state definitely in the absence of a positive sputum that he has tuberculosis, you feel very sure that he does have it, and the only safe thing for him to do is to treat himself as if he were a consumptive.

(5) *Don't forget that practically all pleurisy, wet or dry, of idiopathic origin, are tuberculous.*

This statement does not, of course, include pleurisy following or accompanying pneumonic or rheumatic processes or those due to trauma. It should also be borne in mind that many of these tuberculous pleurisy are caused by a very mild and non-virulent type of organism. I do not believe that every patient with a pleurisy should necessarily be at once packed off to a sanatorium; I do believe, however, that he or she should be made to understand definitely and clearly the exact state of affairs, that the process is due to tuberculosis and that careful supervision and watchfulness are necessary to prevent disaster.

(6) *Don't forget to look elsewhere than the lungs.*

Scars in the neck, or signs of tuberculosis in other parts of the body may give you the best of evidence. Make your routine physical examination as thorough as possible.

(7) *Don't base your diagnosis on x-ray evidence alone.*

I feel very strongly on this point. Whereas the x-ray, properly interpreted by an expert in his line, can give valuable evidence as to the extent of any given lesion, we must always remember, however, that the x-ray deals simply in lights and shadows, and that it gives no information as to whether any given process is active or inactive, old or recent. The x-ray is a valuable adjunct to our means of physical examination; it should never take the place of our older, well-known methods.

(8) *In adults do not place any value on the skin tuberculin test, whether positive or negative.*

In patients over 18 or 20 years. I would pay absolutely no attention to a positive or negative skin tuberculin reaction. As far as the subcutaneous test is concerned, my best advice to the general practitioner is to leave it alone, and let those only perform this test who are qualified by experience and the nature of their training to do it properly, and to interpret its results wisely.

(9) *Don't forget that chronic bronchitis, influenza, bronchiectasis, emphysema, asthma, and other chronic and sub-acute lung conditions still exist and will continue to exist, and that they often resemble pulmonary tuberculosis.*

In these days when medicine is made a public

matter, and educational campaigns in suppressing tuberculosis and other diseases are carried on, our younger and enthusiastic doctors, particularly those recently graduated from the medical school or from the hospital, are apt to find tuberculosis everywhere and apparently to forget the existence of these other conditions.

At a recent meeting, Dr. John L. Morse of this city voiced this sentiment when he remarked that he has to spend much time among his students in assuring them that every child with a cough did not necessarily have consumption and that every baby with the snuffles did not invariably have syphilis. These points are worth remembering.

(10) *Don't forget that the reverse of the above is also true.*

While it is true that the conditions mentioned in the last heading often resemble pulmonary tuberculosis, and that many patients are given the stigma of that disease quite unjustly, it is, of course, evident to everyone that much more harm is done by quieting the patient's fears with the words "chronic bronchitis" or "influenza," when he really is consumptive.

(11) *Don't forget that people may be run down, tired, weak, etc., without having consumption.*

Here again there are the two sides to the question. While the diagnoses of debility, neurasthenia, and "run down condition," anemia, etc., are far too often given, and in far too many cases simply mean ignorance on the part of the doctor, there is, nevertheless, a growing tendency to cry out, "This is tuberculosis!" the instant any one of us gets below par in any way. There are clinics in Boston which I would hesitate to attend if I happened to have a bad cold, because I feel very sure that I would at once be called a consumptive, and that an application would be made out for me to go to Rutland. It is undoubtedly true that many of those periods which most of us have gone through, and which we have called being "run down"—usually in the spring—are due to a slight awakening of a hitherto latent tuberculous focus. It is dangerous, however, to carry this too far. The shop-girl, tired from the Christmas rush, may resemble a consumptive in many ways. It is needless to mention other examples of this condition of affairs.

DIAGNOSIS IN CHILDREN.

Diagnosis of early tuberculosis in children differs in many important details from that in adults. The general underlying principles, however are the same. The more important points I have tried to emphasize in the following pages:

"DO'S."

Remember the following points:—

(1) *Remember the difference between tuberculous infection and tuberculous disease.*

It is extremely important for every doctor to have a clear idea of the difference between tuberculous infection and tuberculous disease. It is a startling fact, but undoubtedly a true one, that by the time 80 or 90% of us reach the age of 15 years, we are already infected with tuberculousis. The mere fact that the great majority of us, however, remain strong and healthy, and live at least an average life-time, shows clearly that this tuberculous infection does not necessarily imply disease.

(2) *Remember the frequency of tuberculous infection.*

This I have emphasized above. Autopsy statistics and evidences based on reliable tuberculin tests have shown only too clearly the impossibility of escaping the tubercle bacillus. All we can do is to reduce to the smallest amount possible the number of bacilli that are taken into the body, and so to live that this tuberculous infection remains a quiescent and harmless process.

(3) *Remember that in children tuberculosis is primarily a disease of the glandular system.*

Whereas in infancy tuberculosis takes the form of a general septicemia, and is rapidly fatal, in the years of childhood it primarily affects the glandular system all over the body. It is only when this first line of defence is broken through that the lungs or other organs are affected.

(4) *Remember the importance of exposure, and that bovine as well as human sources are of importance.*

This is particularly important in the case of children. The modern campaign for clean milk has emphasized the fact that bovine tuberculosis in children, particularly of the glandular system, is often due to tuberculous milk. While there is wide variance as to the amount of tuberculosis due to this cause (up to 75%, according to English; and down as low as 5%, according to German investigators), it is, nevertheless, doubtless true that a very considerable proportion—probably 15 or 16%—of cases of tuberculosis in children comes from a bovine source.

(5) *Remember that in children by the time the lungs themselves are involved, the disease is far advanced.*

One of the greatest steps we have made in the diagnosis of this condition in childhood is our increased familiarity with bronchial gland tuberculosis. Whereas in adults, as I have said before, it is stretching the truth a bit to state that a patient must be past the incipient stages if we find tubercle bacilli in the sputum, and definite signs of a consolidation at one apex, in the case of children, however, it is only too true. We must make the diagnosis long before the pulmonary tissue itself is involved. In these real early cases one rarely finds signs at the apices. It

is by means of a positive cutaneous tuberculin test, the x-ray, perhaps slight interseapular dullness, sometimes enlarged veins on the chest, frequently a positive d'Espine's sign, combined with constitutional signs and symptoms, on which our diagnosis is based.

(6) *Remember the importance of constitutional signs and symptoms.*

In children, as in adults, the careful study of these signs and symptoms, which show that the whole body and not merely the lungs are sick, will offer the most reliable information.

The principal constitutional signs and symptoms are ease of tire, the loss of weight or failure to gain weight, pallor, malnutrition, and debility.

One of the superintendents at a Massachusetts State Sanatorium has gone so far as to state that in his opinion ease of tire and interseapular dullness alone justify a "tentative" diagnosis of tuberculosis. While I do not for a minute agree with this statement, even making the fullest allowance for the word "tentative," I do feel that if a child is pale, has lost weight, has slight fever, and at times a slight cough and in addition shows certain signs in the lungs, that a diagnosis of probable tuberculosis is justified, although I would not on such evidence alone call the child a consumptive.

(7) *Remember that, while in adults there is no cough characteristic of tuberculosis, in children there may be present a cough which is more or less characteristic of bronchial gland enlargement.*

These bronchial glands are situated at the root of the lungs, and if they attain sufficient size, may press on the trachea, the large bronchi, or on nerves, and thereby cause a paroxysmal, strident, brassy cough, usually without sputum, often closely resembling whooping-cough.

(8) *Remember that a positive skin tuberculin reaction is of infinitely greater importance in children than in adults.*

Dr. Orville F. Rogers of this city has recently made a careful study of this point from a fairly large number of cases at the Massachusetts General Hospital. He has come to the conclusion with which I would strongly agree, that in children of five years or under, a positive skin test is good evidence of active tuberculosis, and that such children are not apt to live long. Furthermore, that in children ten years old or under, a positive skin test means, on the whole, a greatly increased mortality from tuberculosis. The value of the positive test becomes less and less with increased age.

(9) *Remember that the x-ray in children may show enlarged bronchial glands, but that it does not prove these glands to be necessarily tuberculous.*

As I said in discussing the x-ray in adults, it gives no knowledge as to the etiology of these

glands, or to whether they are active or inactive, old or recent. We have been far too apt to take it for granted that glands as shown by the x-ray and by a positive d'Espine's sign are necessarily tuberculous. We are now learning that such enlarged glands may be present following any ordinary acute bronchitis, or any acute infectious disease.

"DON'TS."

Don't forget the following points:—

(1) *Don't fail to realize the responsibility you are taking in stamping a child as tuberculous.*

I feel very strongly on this point. I do not feel that it is at all fair to the child, to the parents, or indeed, to the community to stamp every child who is run-down, and who has a slight cough, as a consumptive, and to send him or her to a tuberculosis hospital or sanatorium.

(2) *Do not forget in cases of doubt that it is possible, and far better, to institute proper treatment without casting the stigma of tuberculosis.*

Nowadays, when the public in this state, at least, is fairly well alive to the need of preventive medicine, it is perfectly possible to put the child on a proper line of treatment, which will not only help to arrest his tuberculous process, if there be one, but will also improve his general condition and eradicate whatever germ may be in his system, without using the words "consumption" or "pulmonary tuberculosis."

(3) *Don't make up your mind beforehand as to what you are going to find.*

It ought not to be necessary to speak of this. Unfortunately, however, our minds are apt to run in certain channels. I personally have to guard constantly against this, and I know there are numerous other doctors who have the same tendency.

(4) *Don't forget that while a positive d'Espine sign is good evidence of enlarged mediastinal glands, it does not prove that they are tuberculous.*

I have spoken of this before, but the point is an important one. A positive d'Espine sign, or, in other words, bronchial whispered voice sounds, heard below the level of the fourth dorsal vertebra, is good evidence that the mediastinal glands are enlarged. It is not safe, however, from this sign alone to draw any further conclusions.

(5) *Do not expect to find marked signs in the lungs in every case of bronchial gland enlargement.*

This diagnosis is a difficult one to make. A type case is characteristic. Substernal dulness, interscapular dulness, enlarged veins on the chest, glands in the neck, and paroxysmal, brassy cough, make evident the underlying condition. In most instances, however, you must base your diagnosis on far less than this.

(6) *Don't forget that processes due to influenza, the pneumococcus, and other organisms are common in children, and are often mistaken for tuberculosis.*

Little patches of consolidation, due to either influenza or the pneumococcus, may simulate in every way one due to tuberculosis. While the treatment is approximately the same, the prognosis is, of course, very different. It is well to bear this in mind, especially in those cases where the lung signs are marked, but the constitutional signs and symptoms very slight or absent.

(7) *Don't forget that improper feeding, diseased tonsils, and increased adenoid tissue, a chronic middle ear, and other conditions may simulate tuberculosis.*

In other words, this simply means that your routine examination must be as thorough as possible; that you must not take it for granted that tuberculosis is the cause of a child's run-down condition, but must always be broad-minded enough to realize that other factors may be at work, and may adequately explain the present state of affairs.

(8) *Don't forget that your diagnosis rests, not on one or two striking signs and symptoms, but on an accumulated mass of simple details.*

In other words, after you have been over the case, have the evidence down in writing, if possible; if not, clearly in your mind;—and give it all due consideration before you come to your final conclusion. Do not be carried away by one or two striking points, whether negative or positive.

(9) *Do not forget to be frank and open with the parents, and to explain to them the exact situation.*

The days of mystery in medicine are passed. I find it, personally, far better to take the parents into my confidence whenever possible,—to explain to them if I am in doubt as to the state of affairs, exactly why I am in doubt; to explain to them why I am demanding that certain things be done, and advising a certain course of treatment. I am sure that I thereby get better results than I would if I were simply to say, "Do thus and so,"—without giving my reasons for so doing.

The above "do's" and "don'ts"—points to be remembered and points not to be forgotten—are, I believe, the more important features in the diagnosis of early tuberculosis. I sometimes wish that a large chart could be prepared, which could be hung up in every physician's office, so that he would be forced to see it every day, and to have it in front of him whenever he examined a patient. A mental chart, to be given a prominent place in every doctor's mind, will serve the purpose still better. I sincerely hope that these few somewhat elementary remarks of mine may serve to act in this capacity.

STUDY OF 260 CASES OF ACUTE APPENDICITIS AT THE MASSACHUSETTS GENERAL HOSPITAL.

By LINCOLN DAVIS, M.D., BOSTON,

Assistant Visiting Surgeon.

As was said in a discussion on acute appendicitis at a recent meeting of the Surgical Section of the American Medical Association, the last word has not yet been said on acute appendicitis. Yet there is at the present time quite substantial agreement among surgeons as to when and how to operate for this condition.

There remains something to be said, however, on this subject as long as cases with perforation and abscess continue to come daily to our large hospitals. As Dr. J. M. T. Finney¹ forcibly expressed it: "The last word has not been spoken, or will it be spoken, until we have 100% recoveries. . . . When a death occurs from appendicitis it is *prima facie* evidence that somebody has made a mistake. When pus is found in appendicitis, it is *prima facie* evidence that somebody has blundered. It is not always the physician or is it the surgeon. . . . No case of appendicitis should progress so far as the formation of pus."

The prime factor in the mortality of appendicitis is delay in diagnosis. This threadbare doctrine must still be preached to the laity and the profession. Another factor in the mortality is even less excusable is the pernicious custom of administering a purgative early in the attack. In at least a third of the cases which form the basis of this report, violent cathartics had been administered before the patient came to the hospital. Often the castor oil or salts are taken on the initiative of the patient himself or his family, but, unfortunately, the family doctor, in spite of all that has been said on the subject, still continues to commit this serious offense. However desirable it might seem theoretically to empty the cecum by a cathartic in the earliest stages of an attack of appendicitis, when it might be assumed that there is merely swelling and congestion of the appendiceal mucous membrane, an enormous practical experience has taught surgeons that it is utterly impossible by any clinical sign to be sure of just what the condition of the appendix is at any given moment. How often the medical consultant, misled by the mildness of symptoms, lack of fever and pain, etc., is surprised and horrified to find at the time of operation that the appendix has already perforated. Appendicitis is notoriously insidious. In a few hours the mildest attack may break forth into the fulminating type. Who can say at any given moment that the appendix is not engorged and tense with acute inflammation, ulcerated and perhaps gangrenous and about to perforate? With such uncertainty as

to the actual state of inflammation in the appendix, what folly, to use no harsher term, to call into play deliberately the dangerous forces of vigorous peristalsis.

Before actual macroscopic perforation occurs, there is a migration of bacteria through the wall of the appendix which causes a localized peritonitis, with plastic exudate, and adhesions of the adjacent coils of intestine about the threatened locality. This is a protective process on the part of nature which is preparing to wall off and localize the flood of septic material which is poured out upon actual perforation.

The ideal treatment for acute appendicitis, of course, is to remove the appendix while the inflammatory process is still confined to within its walls, and thus forestall perforation. This, unfortunately, is not always possible on account of obscurity of diagnosis, objections on the part of the family, lack of necessary surgical skill at hand, etc. Granted that prompt operation is the logical treatment for acute appendicitis just as soon as the diagnosis is made, it should be the aim of the physician to promote, or at least not to hinder, the protective efforts on the part of nature while making the diagnosis or awaiting the arrival of the surgeon. This is done by the withholding of food and cathartics, unloading the lower bowel by enema if necessary, and checking peristalsis by small doses of morphine. The disastrous results of violent purging may be readily conceived in premature perforation of the appendix, before the protective plastic adhesions are formed; the tearing apart of such soft adhesions, should they already have formed, and the flooding of the peritoneum with the septic contents of appendix and cecum. Peristalsis not only hastens perforation and prevents localization, but also increases the amount of septic intestinal contents poured out.

Now it must be said in justice to the doctor, that a cathartic is seldom given after the diagnosis of acute appendicitis has been made, except by the few case-hardened sinners who attempt to "scatter" the inflammation by a purge.

The average general practitioner sees perhaps 50 cases of bellyache to one of appendicitis, and castor oil is a time-honored and ready remedy for the former. Appendicitis should be suspected in every case of abdominal pain and a cathartic given only when it can be absolutely excluded. It should be a rule never to give a cathartic for acute abdominal pain with fever. Use an enema instead. This is better treatment even for a bellyache.

About fifteen years ago there was much criticism by surgeons of general practitioners for giving morphine in suspected cases of appendicitis, thereby masking symptoms and delaying diagnosis. This criticism had a most marked effect, so that today practitioners pride themselves on the withholding of morphine in their cases, using an icebag or other local anodyne instead. The preliminary administration of morphine is now quite unusual in cases coming into the hos-

pital. As a matter of fact, after the diagnosis is made, the administration of morphine is not at all bad treatment; its administration should not, however, delay the operation. Just why general practitioners have taken the criticism as to the use of morphine so to heart, and yet disregarded the ten times more serious charge of purging, is difficult to understand.

This series of 260 cases includes my entire personal experience at the Massachusetts General Hospital. With the exception of one case operated on during internship in 1899, the cases date from 1905, with increasing numbers each year, through my last service in 1914. Only definitely acute cases are included; no cases of the subacute, chronic or relapsing type are counted in this series. It does, however, include all cases of general peritonitis arising from the appendix, even cases in which the diseased appendix was not seen, but in which the clinical diagnosis was evident. Furthermore, every case seen was operated upon, the operation being immediate in all but four cases, two in which preliminary Ochsner treatment was tried for a short time, and two other cases in which the patients were kept over night under an incorrect diagnosis. That these cases were all of the acute type is attested by the fact that in all but 12 drainage was used. There may have been, and probably was, an excess of caution in this direction. When the disease is strictly confined to the appendix itself, drainage is probably not necessary, but personally I have felt safer when there was fever and leucocytosis, with fibrin on the intestine and cloudy fluid about the appendix, to leave in a cigarette drain. It weakens the wound hardly at all if a muscle retracting incision is used and it is removed early, while it is very conducive to one's peace of mind.

The appendix was removed in 244 cases, an attempt always being made to do so, unless the general condition of the patient or the local conditions seemed to forbid. The appendix was reported perforated in 87 cases, gangrenous in 92 cases, ulcerated in 11 cases, acutely inflamed and swollen in 52 cases. In one case of general streptococcus peritonitis the removed appendix was reported as not inflamed. No other definite source of infection was found, although the seminal vesicles were suspected. This case probably should not be included here, though clinically it was typical of appendicitis.

In 16 cases the appendix was not removed. In 13 of these, large localized abscesses were merely drained without special search for the appendix; in 2 cases the abscess was drained by rectal puncture. In 3 cases of severe general peritonitis, the peritoneal cavity was merely drained without search for the appendix. There were all together 136 cases, over one-half the entire number, in which there was pus outside the appendix in the peritoneal cavity. In 108 cases the pus was localized in one or more abscesses. In 28 cases pus was free in the peri-

toneal cavity as far as the exploration permitted the determination of this fact. In very many other cases there was free turbid fluid, which was not regarded as true pus.

As previously mentioned, an operation was performed in every case seen; the operation was immediate in all but 4 cases. A large number were performed at night. Fifteen patients died, a mortality of 5 $\frac{3}{4}$ %.

A study of the 15 fatal cases shows that 7 of them, Nos. 192953, 171254, 170833, 169862, 176985, 196620 and 195054, exhibited all the signs of severe general peritonitis before operation, viz., general abdominal rigidity, tenderness, distention, vomiting, poor pulse and great prostration. They varied from the third to the sixth day of the disease. They were recognized as desperate risks before operation. Immediate rapid operation for drainage and incidental removal of appendix, if readily accessible, was undertaken in 6 cases. The presence of diffuse peritonitis was confirmed in all. There was no rally in any of these cases after operation, and death ensued within a few hours in all, except one case, in which death occurred after five days. In one case Ochsner treatment was tried for four days, with some improvement at first, then the patient began to fail again, with rising pulse and temperature, vomiting and failure to retain salt solution. He was then operated on as a last resort and 2 or 3 pints of pus drained from the abdominal cavity, after which he sank rapidly and died within a few hours.

It is my firm conviction that none of these seven cases could have been saved by any operative procedure. Whether or no Ochsner treatment might have resulted favorably in any of them, it is impossible to say. It was tried in only one other case, No. 171338, a boy of 8 years, who entered the hospital on the fourth day of the attack, desperately sick, with vomiting, distention, pulse 170 and cold extremities. He was put on Ochsner treatment for four days and made remarkable improvement; pulse fell and temperature rose, vomiting ceased, and at the end of four days he seemed to have reached the turning point and to be again on the downgrade. A rapid operation was done, with drainage, and he made a stormy but ultimate recovery.

Of the 21 other cases in which evidence of diffuse purulent peritonitis was found at operation, there were 14 in which there were severe pre-operative signs and symptoms of peritonitis. One or two of these were almost, if not quite, as sick as some of the 7 that died. It is a striking fact that over half of these cases were in children. As a result of this review I am convinced that the Ochsner treatment has a distinct, limited, but precious field of usefulness. As a general rule I prefer to apply it after operation rather than before, but as its author requests, we can at least make use of it in the cases in which we feel that operation will surely result fatally. I am inclined in the future to give it a

more liberal trial in those cases at about the third or fourth day, when perforation has just taken place and which are temporarily overwhelmed and prostrated by the dose of septic poisoning.

Of the 8 remaining fatal cases there was no particular indication of a bad prognosis at the time of operation. One case, to be sure, No. 90581, had a temperature of 104.6 at time of entrance before operation, on the third day of the disease. He had a gangrenous appendix wrapped in omentum. The appendix was removed and stump and pelvis drained. Chills occurred on the second day after operation and continued thereafter. He finally died six weeks later, of pyelophlebitis, plus abscesses of liver. Of the 7 other fatal cases, 4 cases had well developed and fairly well localized abscesses, with symptoms of from four to eleven days' duration, 2 cases had more or less localized peritonitis and one case had a high retrocecal gangrenous appendix with very little pus. The appendix was removed in all of these cases, and in 2 of them it may fairly be objected that the dissection necessary to permit of this was contributory to the spreading of a fatal peritonitis. In one other case the result might be attributed to technical error, that of a large pelvic abscess with fibroids of the uterus. A median incision was made and one tube and ovary removed before the causative factor, a gangrenous appendix, was found and removed. A fecal fistula of the small intestine developed in this case; three unsuccessful attempts were made to close this, and the patient finally succumbed on the 24th day. In this case and one other in which marked costo-vertebral tenderness led us to suspect a kidney lesion, operation was delayed over night. I do not think that the delay in either of these particular cases was an important factor in the result. Such errors of diagnosis, however, occurring in a great hospital, with every facility for investigation at hand, should incline us to some charity in condemning the medical consultant for occasional delay in diagnosis in the patient's home. In the other fatal cases, four in number, the technic of operation was the same as had been carried out in a great many similar cases with success. It can only be said that for some reason the infective process spread and involved the rest of the peritoneum. One of the cases was complicated by post-operative bronchitis and severe secondary hemorrhage from the epigastric vessels on the eleventh day. In 2 cases there was an unusual amount of foul, bloody oozing from the wound, not sufficient to be considered a hemorrhage, but very likely a factor in spreading infection.

The question of when not to remove the appendix in any given pus case is one requiring the nicest degree of judgment. As a rule I believe that it is possible to remove the appendix without undue increase in risk in the great majority of cases. On the other hand, when the patient is old or in poor condition, or the appen-

dix not readily accessible, there is no question but that we should content ourselves with simple drainage.

The prevention of pylephlebitis is undoubtedly often beyond our power. When a wad of inflamed omentum is wrapped about a gangrenous appendix, I believe it is advisable to ligate and resect a generous portion of the omentum with the appendix, especially if there is a very high temperature or chills. Furthermore, having watched the harrowing progress of one case of pylephlebitis of my own, and another in the hands of a colleague, I feel that I never would again stand by without making some attempt at arresting the septic process by ligation of the affected tributaries of the portal vein. The successful cases of Wilms² and Braun³, and the experimental work of Neuhof⁴ and others have opened up suggestive possibilities in this line.

Besides the very serious complications of peritonitis and pylephlebitis, already considered, other complications occurred as follows in 23 cases, often two or more associated together in a single case: Residual abscesses developed in 8 cases; pelvic, 5 cases; abdominal, 2 cases; subdiaphragmatic and abdominal, 1; pneumonia, 4 cases; broncho-pneumonia, 1 case; bronchitis, 1; secondary hemorrhage from epigastric vessels, 2; intestinal obstruction, 2; mental depression; salpingitis, 1; thrombosis of leg, 1; fecal fistula, 2; scarlet fever, 1; miscarriage, 1; infectious diarrhea, 1.

Secondary operations were performed for complications in 13 cases, not including 3 cases in which enterostomy was done through the wound in nearly moribund general peritonitis cases. I have yet to see any benefit from this procedure in such cases. Residual pelvic abscesses were opened in 3 cases by vaginal puncture, once by rectal puncture. In 4 cases abdominal incisions were made for residual abscesses, in 2 cases in the left flank. In one of these cases there were 3 such operations, one being for subdiaphragmatic abscess. Two cases of intestinal obstruction required secondary operation for freeing of adhesions, and in one case enterostomy; both resulted in cure. Three unsuccessful attempts were made to close a high fecal fistula in a badly infected case with fatal issue. The other case of fecal fistula closed spontaneously. Exploratory laparotomy for liver abscess was done in one case. Appendectomy was done in one case in which the appendix abscess had merely been drained at the first operation.

In the after-treatment of cases the Fowler position has been used when there has been any suspicion of existing or impending peritonitis. Rectal saline solution is given either by continuous seepage, as recommended by Murphy, or more usually at intervals. Cathartics are shunned during early convalescence, the bowels being moved by enemas only. Cigarette wicks which are used almost exclusively, are left

when pus is present for seven to eight days undisturbed. I have never seen any trouble from leaving them too long, but, on the other hand, have observed serious consequences from their too early withdrawal. They are never changed while the patient is distended, except as a last resort. After seven or eight days, a fairly firm sinus tract of granulation tissue has formed, and the original wick may easily be replaced by a smaller one of gutta-percha tissue to an equal depth. The gradual shortening of wicks is not practiced. When the discharge has become small in amount the wick is removed entirely, perhaps by the tenth to the twelfth day, depending on the nature of the case. Drainage through the wound, usually at the lower end, with suture of the upper portion, has been found very satisfactory. The occurrence of secondary hemorrhage from the epigastric vessels, which was seen twice in this series, once it was of trifling extent only, might be claimed to be due to the presence of the drain, and urged as an argument against the method. It can be obviated by ligating those vessels in all drained cases, when they are exposed at the edge of the wound. When residual pelvic abscesses occur, as they will occasionally, in spite of all precautions, I wish to emphasize the value of vaginal or rectal drainage. This has been considered in previous papers.⁵

Of the 245 patients who survived the operation, data are at hand as to their condition in 86 cases at the end of one year. There were 4 cases of hernia in the scar; 1 case reported as having a weak scar and 3 bulging. In 4 cases there were inguinal hernias, in 1 case there was double hernia. Two cases had persistent sinuses. One patient had pain in the side and 2 complained of weakness in the side. In the remaining cases the results were entirely satisfactory.

The study of this series of cases has brought out nothing new. It merely emphasizes certain points already familiar, but which perhaps cannot be too often reiterated. The great factor in the mortality of acute appendicitis is delay; delay in making the diagnosis; also to a less degree, delay after the diagnosis is made. A second factor is the practice of giving a purge during the acute attack. There is still need of preaching these doctrines to the laity and the profession. A temperature above 102.5 in acute appendicitis is distinctly rare. In the few cases in which it occurs it is of bad prognostic import. Cohnsner treatment has a distinct field of usefulness. The operation in cases involving peritonitis should be directed to removal of the primary focus if accessible, and to securing of drainage with as little disturbance as possible of the general peritoneal cavity. The use of rubber tissue or gutta-percha wicks, rectal saline, Fowler's position, the avoidance of catharsis by mouth, and the leaving of wicks undisturbed, have simplified and safeguarded the after-treatment enormously.

OBESITY AND MALNUTRITION.*

BY WILLIAM E. PREBLE, M.D., BOSTON,

Assistant Physician in the General Medical Department of the Boston Dispensary.

Scope of Paper.

In considering this subject, only what might be called primary obesity and primary malnutrition will be discussed—that is, these conditions occurring as complications or sequelae of other diseases will not be considered.

The two conditions really belong under one heading, as in both the question is simply one of ratio of amount of nourishment ingested to the amount burned up by the bodily activities. The undernourished individual takes too little of the right kind of food, and the fat person takes too much.

MALNUTRITION.

We may, then, consider malnutrition as a condition due to a continued undersupply of nourishment, in either amount or kind. Our type case is a thin, active, nervous, constipated young woman with a poor appetite, often suffering with headaches, perhaps with indigestion, and in some cases having a visceral ptosis. She is usually a wage earner, and has frequently consulted physicians to see if she has tuberculosis, cancer, or some blood disease. She has been given iron, cod liver oil, malt, and Fellow's Syrup of Hypophosphites, and may have been accused of having latent tuberculosis, or, if she has consulted a strictly up-to-date practitioner, intestinal stasis.

Etiology.

The etiology of this condition is primarily a continued undersupply of suitable food, taking into consideration the energy out-put of the patient.

Frequently appetite is variable or entirely absent. In some cases the strenuous life is to be blamed. The patient sleeps in the morning until the last possible moment, hurries through breakfast or omits it altogether, takes insufficient time for lunch, (perhaps imbibing it at the soda fountain), and is so tired at dinner time that she cannot eat and perhaps is not able to digest a "square meal." Social activities may claim time in the evening that should be devoted to rest.

* Read before the Fall River Medical Society, February 3, 1915.

Ignorance of food values and of bodily needs frequently plays a part, and nature's requirements are neglected with the usual result.

Pathology.

Strictly speaking, there is nothing pathological in these cases. There is simply an insufficiency of adipose tissue, and perhaps a mild anemia.

Diagnosis.

In the type mentioned above we must first rule out all chronic disease. A careful history and searching physical examination, with such laboratory aids as may be indicated, will definitely dispose of all question of tuberculosis, nephritis, syphilis, malaria, the primary anemias, and hemorrhage from a peptic ulcer, the uterus, or hemorrhoids. Careful computation of the daily caloric intake will settle the diagnosis, as a rule.

Prognosis.

The prognosis is good, with proper treatment.

Treatment

The general indications are—to increase the caloric intake and, if possible, decrease the energy output.

1. **STUDY OF CASE.** The first step in the treatment is a careful study of the dietary and other habits of the patient, including the amount and kind of exercise; the number of hours of sleep and, in general, the ordinary daily régime of the patient.

2. **CALORIC INTAKE.** The next step is to increase the caloric intake. Insist upon a hearty breakfast, whether it is desired or not. Most of our tastes are merely habits, and may be changed with surprising ease, if we persevere. Sufficient time must be taken for luncheon and dinner. Attention must be paid to the caloric value of foods. The patient must be taught to take plenty of butter on bread and vegetables, cream whenever obtainable, and the fatter kinds of meat and fish. Roast beef, for instance, has nearly three times the caloric value of chicken, and mackerel almost exactly twice that of haddock. A glass of milk or a raw egg may be taken immediately after finishing each meal, and on retiring. Luncheons should not as a rule be given between meals, as they lessen the appetite for the next meal.

3. **PROTEID.** Proteid should be given to exceed slightly the amount required to maintain nitrogenous equilibrium—say 70 to 90 grams—as many of these patients are slightly anemic.

4. **DRUGS.** Drugs help in stimulating the appetite and act as general tonics. The bitter tonics and hydrochloric acid before meals are valuable to stimulate the appetite, and iron and arsenic are indicated, if the patient is anemic.

5. **SLEEP.** At least nine hours' sleep should be insisted upon, and if possible a short rest after luncheon and dinner should be taken.

6. **EXERCISE.** Only moderate exercise should be prescribed, and that should be taken out-of-doors. Riding and walking are the best forms.

7. **EDUCATION.** The most important factor of all is to teach the patient how to live, as the best results are impossible without hearty co-operation of physician and patient. Under such favorable circumstances, a patient should gain on the average, about one pound per week.

I mentioned above the fairly frequent occurrence of ptosis of the abdominal viscera in this class of patients.

Ptosis, if present, is not necessarily an important factor. Unless there is definite stasis, the condition need not as a rule be considered in treating the case. If the stomach is dilated and does not empty properly, or if there is a prolapsed and dilated caecum, with stasis at this point, the patient does not belong in this class. The x-ray settles this question.

OBESEITY.

At just what point obesity begins is very hard to define. Without trying definitely to settle this point, we may say that obesity is an increase of adipose tissue beyond the needs of the organism. Fat is stored-up nourishment, and a certain amount is conducive to the best working of the bodily activities. An excessive amount throws extra and unnecessary work on the various organs, both as a dead weight that must be carried about, and as an obstruction to many bodily functions.

Our type case here is a middle-aged person who is gradually reducing his physical activities as his income increases. He takes just as much food, and of a rather richer quality than formerly. He may ride where formerly he walked. Sometimes he takes pleasant but stimulating drinks of high caloric value, where formerly water sufficed. Quite as frequently the patient is of the female sex, but the factors producing the increase in adiposity are the same.

Etiology.

Habitual excess in the ingestion of nourishment, together with lessened physical activity, are the usual etiological factors. Rarely other causes may be found, such as atrophy of the thyroid, with the resulting myxedematous condition; disease of the posterior lobe of the hypophysis,¹ castration, and menopause. Some authorities cite a racial factor, as the Jewish people seem inclined to adiposity, but it is a question if this is not due to habits of eating, rather than to any unusual metabolism. Lastly, some authorities ascribe a perverted metabolism as the cause in some cases. If this is ever a causative factor it may be disregarded in treatment.

Pathology.

Leaving out the question of just where pathology begins, we may describe the conditions resulting from gradually increasing obesity in three classes.

1. In the early stages there is a deposition of fat in the subcutaneous tissues, mediastinum, abdomen, pericardium, between the muscles, and in practically all the bodily tissues.²

2. As the supply of fat increases, the muscles, including the heart muscle, become infiltrated and somewhat weakened. The action of the heart and diaphragm are mechanically interfered with, and the result is the so-called fatty heart. New blood vessels are formed to nourish the fatty tissue³, and the amount of tubing through which the heart must force the blood is increased, thus increasing the work of the heart, and consequently raising the blood pressure³.

3. As the accumulation of fat continues, there is finally produced a condition of fatty, or fibro-fatty, degeneration of the heart and blood vessels, and skeletal muscles.⁴ In these cases the damage done is irremediable. The fat may be removed, it is true, but the damaged muscles, viscera and blood vessels can never be rejuvenated.

Sequelae.

Let us consider briefly some of the sequelae of this excessive accumulation of fat. Respiration is interfered with by the fat above and below the diaphragm, and oxygenation suffers. The heart is embarrassed and its work increased, both by the extra weight carried about by the patient and by the formation of new blood vessels in the fatty tissue. The blood pressure is raised. As the heart becomes slightly incompetent, there develops a congestion of the great viscera, and oedema of the dependent parts, with resulting interference with the capillary circulation. Two of the early signs of heart strain are nocturia (Strauss) and pitting of the ankles on pressure. Many of these patients are "bilious," which simply means that they are overloading their digestive apparatus, and the congested stomach, intestines and liver are protesting.

The congestion of the kidneys is manifested by a slight amount of albumen, rarely with a few casts, which disappears when the congestion is relieved, conclusively differentiating this condition from the chronic nephritis that these patients are so often accused of having.

Arterio-sclerosis may develop as a result of the increased blood pressure⁵, and atheroma from the deposition of fat in the musculature of the arteries. In extreme cases there may develop a cardiac cirrhosis of the liver, or chronic interstitial nephritis, from the long continued congestion of the liver and kidneys, or a degenerative myocarditis, due to the fatty degeneration of the heart muscle⁶. Diabetes, gout and a sort of vascular rheumatism, due to the impoverished blood supply of the relatively non-vascular tissues about the joints (Smith), are

frequent sequelae. A very common and relatively early complication is a mitral regurgitation, due to a slight dilatation of the heart and a stretching of the papillary muscles or mitral ring. A systolic murmur may often be brought out by a little exercise. In some cases this entirely disappears when the strain on the heart is removed.

A patient with slight dyspnoea, a little oedema of the lower legs, a little albumen in the urine, and a blood pressure too near the 200 mark, is often told by his family physician that he has Bright's disease, and must take a light diet, *i.e.*, he must eat very little meat, and live chiefly on bread, cereals, vegetables, milk and eggs. This is the worst possible treatment, as a diet of this kind still further increases the accumulation of fat, and aggravates the trouble.

Symptoms.

The symptoms of increasing obesity are those of increasing cardiac strain. We may divide the cases into three classes, corresponding roughly to the three classes made in the discussion of the pathology.

1. The first class are those with the early symptoms of heart strain—slight dyspnoea on exertion, noticed particularly on going up stairs, walking up hill, or after any extra exertion, such as running a short distance for a street car. The blood pressure is slightly elevated. These patients acquire an increasing reluctance to the taking of physical exercise, and as the habits of eating are fixed, there is a decided tendency to take on weight still more rapidly.

2. The second class comprises those who have dyspnoea on slight exertion, nocturia, and slight pitting of the shins on pressure, with markedly increased blood pressure. As these patients have a slight cardiac decompensation, with the accompanying visceral congestion, they are apt to be "bilious," and often go to the physician complaining of indigestion. They are sleepy, especially after meals, and apt to be quite averse to physical exercise. Many of them have rheumatic pains about the joints.

3. The third class are those with the marked pathological changes noted above. There is cyanosis, marked dyspnoea on the slightest exertion, perhaps orthopnoea, and cardiac asthma—in short the classical symptoms of a badly broken cardiac compensation, with degeneration of the myocardium. The blood pressure may be high, or if there is much dilatation of the heart, it may be below normal. There may be sugar in the urine, and there will assuredly be albumen, and probably casts. Ascites may be present if there is a cardiac cirrhosis.

I want to emphasize the point that all of these conditions may develop without any other predisposing factor than the strain on the vascular system and great viscera from excessive and long continued obesity. The end result is a so-called cardio-renal complex.

Diagnosis.

The diagnosis of obesity is made with the office scales and measuring rod. Any marked excess of weight for a given height is obesity. The tables used by the insurance companies⁷ are useful as average figures, but the build of the patient should be taken into consideration. The large-boned, broad-shouldered type should be allowed more weight for a given height than the small-boned, narrow-chested type.

Prognosis.

The prognosis is good for class 1 and class 2 for an absolute cure, if the superfluous weight is removed. Class 3 may be relieved, but the ultimate prognosis is bad. Very stout patients who have not developed marked symptoms are frequently told by physicians that there is no need of reducing as long as they feel well. This doctrine tends to overcrowd class 3. Any great excess of fat should be immediately removed, before the vascular system and great viscera undergo degenerative changes.

Treatment.

The treatment of any obese patient is an individual and specific problem, and must be prefaced by a careful study of the dietary and other habits of the patient. Chronic disease must be diagnosed or ruled out, as we must vary our treatment according to the presence or absence of chronic nephritis, diabetes, serious heart trouble, etc.

The general indications are:

1. To reduce the caloric intake, and
2. To promote oxidation.

Contrary to the statement frequently made in the text-books, advanced age is not a contra-indication for reduction. There is no age limit that we have to consider in the treatment of obesity⁸.

Diet.

PROTEIDS. The amount of proteid given is the first and most important consideration. As the carbohydrates and fats are cut down the proteids must usually be increased to maintain nitrogenous equilibrium. If the kidney function is normal, there is not much danger of a patient taking too much proteid. Chittenden demonstrated that a person of average size may get along on 40 to 50 grams a day⁹, but did not demonstrate that 90 or 100 grams is harmful.

FATS. The fats are reduced. Cream and the fat of meats are prohibited. Small amounts of butter and cheese may be taken. The leaner meats are ordered—veal, lamb, white meat of chicken or turkey—and beef, mutton, goose, etc., allowed occasionally for variety.

CARBOHYDRATES. Sugar, pastry and sweets are prohibited, and the patient is encouraged to get over the sweet habit, if he has it. Bread of all kinds is given very sparingly, and the patient is taught to eat in its place potato, and fruits and vegetables of low percentage carbo-

hydrate content. The patient may be assured that if he will adhere strictly to his diet list, he will soon enjoy his food just as well as he did under the old régime.

If the patient is very fat and very oedematous with considerable dilatation of the heart, he should be put to bed for one or two weeks, and be given eight ounces of skimmed milk every 2½ hours, with the whites of 4 to 6 eggs, and some cooked fruit added each day. The oedema disappears in a surprisingly short time, and the weight will drop from one to two pounds daily. Solid food should be given three or four days before the patient is allowed to sit up. On the ordinary diet the patient should lose on the average about two pounds per week.

Drugs.

Drugs are of little use in taking off weight. In some cases small doses of thyroid may be given, but it is a dangerous drug, and should never be given unless the patient is under close observation. Ovarian extract and potassium iodide are not of much use, in my experience. In the cases with cardiac disease, digitalis, and the other heart stimulants are indicated just as in any patient. Cathartics should be used with judgment. Violent catharsis is never indicated. Patients with oedema may be given moderate doses of the salines with benefit. Patients without oedema need no cathartic if the bowels move daily.

Exercise

Most of the obese patients should take very little exercise. If we remember that all of these patients have overtaxed hearts, we shall see the logic of limiting their exercise until at least part of the superfluous fat is removed. When the heart becomes entirely compensated light exercises may be prescribed.

Baths and Spas

A cool sponge bath with a brisk rub down should be taken on arising, and a tepid bath on retiring. These act as mild vascular stimulants, and promote oxidation. Spas are never indicated for therapeutic reasons. The same, or better, results may be obtained at home. "Boiling out" at the hot springs, or the vigorous catharsis at the sulphur springs, are not important factors in reducing adiposity. The spas that obtain good results in these cases have a carefully regulated regimen of diet and exercise, which is the important factor.

In General.

There are some general considerations that I wish to mention in the treatment of these cases.

Hypertension.

I have already mentioned the effect of adiposity on blood pressure. The increased weight, carried by the patient, the formation of new blood vessels in the fatty tissue, the mechanical interference with the heart and diaphragm, and, in cases with oedema, the interference with the

capillary circulation, seem to be the main factors in imposing extra work on the heart, and hence the immediate causes of the hypertension. As these causes are removed, the blood pressure falls as a matter of course. If it does not fall, there is present some trouble other than obesity—chronic nephritis being the most common one.

Individual Treatment.

Each patient must be considered as an individual. There are no general rules that apply to all patients. Careful study of the case, and an intimate knowledge of food values¹⁰ and general metabolism, are indispensable factors in successful treatment.

Every patient should be supplied with a written list of instructions, and the lists should always be made as liberal as is possible under the given conditions.

Psychic Factor.

The psychic factor must not be neglected. Get the patient to make a fad of following instructions to the letter.

Lastly, when things don't seem to be going right, find the reason—there always is one.

THE RELATION OF ALCOHOL TO ACCIDENTS.*

BY WILLIAM J. BRICKLEY, M.D., BOSTON,

Resident Surgeon, Haymarket Square Relief Station, Boston; Fellow in Surgery, Harvard.

THERE are about 40,000 patients treated each year at the Haymarket Relief Station. These patients come from the emergencies arising in three general groups. There is the Industrial Group, the Transportation Group and the Residential Group.

The Industrial Group, in a general way, includes shops and manufacturing. Here, in the heart of Boston, there are no groups of factories such as are found in Lynn and Brockton. There are no groups of mills such as are found in Lowell and Lawrence. But there are many separate shops and factories. Numerous candy factories, tailor shops, metal-working shops, etc., are in the district covered by the hospital.

The carriers comprise the Transportation Group. These are the elevated, surface and sub-

way railways, railroads, waterborne transportation, both freight and passenger, and the street traffic. The district covered by the Relief Station extends from Sullivan Square, Charlestown, to, and beyond, the new Commonwealth Docks in South Boston; and from Park Square to the North End waterfront. During each working day there are over 600,000 people in this district. The South Station handles 200,000 passengers each working day; the North Station handles 100,000; the Park Street Subway handles 96,000; the Sullivan Square Station handles 130,000 each working day. There are ten miles of busy waterfront in this district, with numerous steamship lines. The Boston harbor excursionists numbered 1,086,000 passengers in 1912. One harbor steamship line alone carried almost 900,000 passengers that year.

The transportation on our city streets, whether motor, horse drawn, or foot passenger, moves under the disadvantages and dangers attendant upon congestion in narrow, crooked streets.

Under the Residential Group are included the homes. These vary widely. Beacon Hill, North End, Chinatown, and Charlestown all lie within the district. Other hospitals care for some of the emergencies, but the Haymarket Relief Station cares for most of them.

With this brief survey of the scope of our field, we can now consider the relation of alcohol to accidents as it has come under our observation.

It may be stated, based upon our experience, that:

- a. Alcohol causes accidents.
- b. Alcohol obscures the diagnosis.
- c. Alcohol increases the danger of infection at the time of the accident.
- d. Alcohol prevents adequate treatment.
- e. Alcohol increases the danger of intercurrent complications.
- f. Alcohol retards the process of repair.
- g. Alcohol gives a poorer end result.
- h. Alcohol increases the mortality in accidents.

a. Alcohol causes accidents.

Under the influence of alcohol, a man falls on the sidewalk, or from a wagon, and injures himself. The probability is present, but extremely small, that he would have so injured himself if he had not been under the influence of alcohol. A longshoreman improperly slings a package of merchandise which falls and injures himself or his workmates. A carpenter improperly fastens a scaffolding which collapses and injures himself or a person passing by. Again, a teamster or a chauffeur, while under the influence of alcohol, injures himself or others in the highway. The intoxicated person turns off the gas in the bed room, then accidentally turns it on. Gas poisoning, explosion or fire follows.

* Read at the annual meeting of the Massachusetts Society of Examining Physicians, Boston, Dec. 19, 1914.

b. Alcohol obscures the diagnosis.

When certain types of injury are suffered by a patient while under the influence of alcohol, it is impossible to make a full diagnosis until the effect of the alcohol has passed off. With contusions of the head producing concussion or contusion of the brain or other intracranial injury, it is impossible in the presence of alcohol to localize or to estimate the extent of the injury. Fractures of the skull associated with alcohol present the same difficulty.

Abdominal injuries are obscured by alcohol. Beginning peritonitis from perforated gastric ulcer or from ruptured abdominal viscera cannot be discovered at once. Three different patients were brought to the hospital days after an injury received while intoxicated, suffering from ruptured bladder. Each was moribund at entrance. Autopsies showed that the condition might have been easily relieved surgically if seen early. The intoxication had obscured the condition.

Alcohol obscures the diagnosis where poison has been taken either accidentally or designedly. Such poisons as would give a distinct odor to the breath may be covered up by the odor of alcohol, and their effects are obscured by the same agency.

The diagnosis of deep-seated trauma of joints or muscles is always obscured to a degree by alcoholic intoxication.

c. Alcohol increases the danger of infection at the time of the accident.

When a man is intoxicated, he does not take proper care of his wound. In his stuporous or irrational attempts to aid himself, dirt and infection enter the wound; or he breaks the skin over a fracture and thereby changes a simple injury into a dangerous one. For example: a drunken man walked about with a compound fracture of the ankle which had the bones protruding through the flesh. He had been walking in the street in that condition.

The intoxicated person permits great blood loss which weakens vitality and makes infection easier.

Another example is that in which a teamster under the influence of alcohol, steps on a rusty stable nail, takes no care of what the ordinary man in his senses would know to be a possible serious accident. Later, infection and maybe tetanus develop from a neglected injury.

d. Alcohol prevents adequate treatment.

Intoxicated persons do not realize the necessity of proper cleansing and suturing of wounds. They do not realize the necessity of proper reduction of dislocations, and reductions of fractures. They do not realize the necessity of proper operations to discover or to repair injuries. Hence, they do not permit the best treatment. No surgeon wishes to assume the legal risk of operating upon an unconscious or upon an irrational patient; therefore, the case waits

and receives palliative treatment only until the patient is sober or until consent for operation is obtained from the proper authority. This interval of delay is often enough to turn the scale against the patient. One case that we recall on this point is that of a man who received a compound fracture of the humerus while drunk. He refused proper treatment and by his own actions made a serious matter worse. He spent over a year in an acute hospital, most of the time in bed and all of the time in pain. He had seven operations under ether and finally got an atrophied, weak arm, when all the humerus had been removed.

Alcoholics cannot or will not swallow drugs as antidotes for poison or for purposes of stimulation. Many alcoholics are quarrelsome and restless. Many persist in undoing the work which the surgeon does for them. They remove plaster casts, or remove splints; they will not tolerate rectal-saline. They hurt themselves in their efforts to get up out of bed, thereby causing secondary injuries to the already injured tissues. They dislocate again the fragments; they tear open the wound, whether such wound is accidental or operative. Until the patient is out from under the influence of alcohol, treatment may not be begun, and certainly cannot be maintained, if such treatment involves uncomfortable or unusual positions or unusual surroundings.

e. Alcohol increases the danger of intercurrent complications.

The injured alcoholic in the wards or at home is far more likely than the sober man to have intercurrent complications. He is far more likely to have secondary hemorrhage, refractures, displacements of fragments. The alcoholic whose vitality is already low by over-indulgence in alcohol, when attacked by what would be an ordinary bronchitis, speedily develops an oedema of the lungs or pneumonia when confined in bed. The alcoholic frequently cannot tolerate necessary feeding, because of alcoholic gastritis. Therefore, the vitality of the patient suffers because proper food cannot be given.

Delirium tremens is a frequent accompaniment of fractures in alcoholics. There may be present only an oedema of the brain, which leaves the patient just irrational enough to attempt movements with the broken bone, or wish to sit up when he should lie still, or to seek to change apparatus which should not be disturbed. Or, the delirium may become so violent that all proper apparatus must be removed, and the patient treated solely for the general condition and at the expense of the local condition. The local results obtained in such cases are not good. Those alcoholics who, because of a small accident are confined to bed, frequently develop pneumonia. With the delirium due to alcoholic oedema of the brain, comes the delirium due to the pneumonia. A delirium tremens patient who develops pneumonia has about 17 chances in 100 of getting well by the ordinary hospital

method.[†] This is not surprising when we consider that those who develop delirium tremens are exhausted and poisoned from the use of alcohol even before they are called upon to combat the toxins of pneumonia. Such patients are likely to keep on their feet until they collapse or are injured.

Accidents that would be trivial, or not especially serious of themselves, become extremely grave because of the pre-existing condition of the patient. In the case of the chronic alcoholic we find the conditions favorable to cause trivial accidents to terminate fatally.

f. Alcohol retards the process of repair.

Any surgeon who has had experience in a large general hospital recognizes that accidental or operative wounds do not heal so quickly nor so well in the alcoholic as in the clean non-alcoholic adult. This retardation of repair is especially marked in injuries to the bones. It is fair to say that the hard drinker takes about 20% longer time to make repair from fractures of the large bones than the non-drinker takes for a similar injury. Lack of proper reduction and fixation where the patient is likely to develop delirium tremens or any grade of the same also causes retardation. One cannot apply proper splints to save severed tendons or severed muscles and cannot maintain the part in fixed unusual positions, when the patient is likely, thereby, to be irritated into an attack of delirium. The surgeon cannot keep the patient quietly in bed for the sake of the injury if the patient's general condition demands that he be sitting up or walking about. Therefore, the process of repair is delayed in starting and the process of repair is slowed down because of the toxic condition of the hard drinker. One must treat the general condition first, then the local condition; whereas in the clean adult, one can attack the local condition at once and adequately.

Because of longer periods of fixation of extremities and of longer periods spent in bed treatment, a greater amount of muscle atrophy and a lessened amount of joint mobility certainly appear. As both of these conditions require time and perhaps manipulations to overcome, they retard the convalescence.

g. Alcohol gives a poorer end result.

Because of delayed primary care of the injury and of deferred adequate treatment, time is lost and the risk of complications is increased. Because the physical condition of the hard drinker is already poor from gastritis or cirrhosis of the liver, or nephritis, etc., the shock and the stress of the accident bear harder upon him than upon a teetotaler. Because the duration of repair is lengthened in the alcoholic, more time is lost.

After the acute phase of the injury is over, and the patient has left the hospital, he seeks to

recover his strength in order to go to work. In this period the patient, who has necessarily been abstinent during the acute phase of his injury, is quite likely to over indulge in alcohol during the convalescent period. He takes a drink to "strengthen" himself, or to relieve his discomforts. This is dangerous for him, and frequently leads to partial or to complete reinjury. For, being in a weakened condition from confinement and from injury, he cannot stand anywhere near his usual potation. If he attempts it, he becomes intoxicated.

The effect of heavy drinking upon a healing wound is very noticeable. Wounds that have almost healed break down and open again. Open wounds increase their discharge, while the edges of varicose ulcers, etc., seem to melt away. Some of this condition is due to the improper strains or to neglect of person or to exposure to which the drinking man subjects himself. An ordinary man lightens his work if he has a pain in a recently healed bone, or about an injured joint; but an alcoholic takes a drink for the same condition and goes on. An ordinary man protects his wound following a partial recovery, but an alcoholic takes a drink and forgets about it. This tends to make the injury chronic. Therefore a poorer end result certainly follows. We get a 60%, 70% efficiency of the part following the injury where we have a right to expect 80% or 90% efficiency with the resources at our command, and the treatment we are able to carry out if conditions permit us to do so.

h. Alcohol increases the mortality in accidents.

By obscuring the diagnosis, alcohol defers proper treatment. This delay diminishes the patient's chance for life when the real conditions are discovered. By increasing the risk of infection, or by neglecting the beginning of the same, a condition is permitted to arise which aggravates the injury and lessens the chance for life.

Alcoholics do not bear surgical shock well. After traumatic amputations and severe lacerations, a longer time is required to bring them back to an operable condition. This necessitates deferring urgent operations. Alcoholics do not live so long after being injured as abstainers do; which is another way of saying that their vitality is less.

The records of the Haymarket Square Relief Station for the year 1911 show that there were 199 patients who died there. Of these deaths, 19 were patients under 21 years. Of those adults who died as the result of accident that year, 38.2% were under the influence of alcohol when they entered the hospital. Of those adults who died by disease that year, alcohol was noted in 36.3%.

In the summer of that year there were 1,082 cases associated with heat, treated here. It was very noticeable that the chronic alcoholics were more prostrated and had a higher mortality than the abstainers.

[†]In fifty-three cases of delirium tremens patients who developed pneumonia, forty-four patients, or eighty-three per cent., died. This was over a four-year period at the Haymarket Relief Station.

In the year 1912, there were 191 deaths, of which 168 were adults. Of the adults who died because of accident 33% were under the influence of alcohol when they entered.

In the year 1913, there were 169 deaths, of which 158 were adults.

Of the adults who died because of accident that year, 48.4% were under the influence of alcohol when they entered.

In the year 1914, there were 132 deaths, of which 110 were adults.

Of the adults who died because of accident that year, 43% were under the influence of alcohol when they entered.

Practically all the severe accidents seen here are fresh,—minutes old, usually. So that, if alcohol is present at entrance to the hospital, it was present at the time of the injury. Great care is exercised to exclude doubtful alcoholic diagnoses and cases in which alcohol was given subsequent to the injury. No such cases appear in the above statistics. Nor is alcohol noted down in all the cases in which it is present. It is noted down only when, being present, it requires treatment or enters into the estimate of the rationality of the patient. It is not entered in the records for statistical reasons, but solely for purposes of treatment.

Many cases are gravely injured or moribund at entrance. The presence of alcohol under such conditions is an unimportant detail, and would be of no service in the treatment. Thus it happens that alcohol is not mentioned in the records even when we are sure it is present.

Not all the injured received here who die from their injuries die in this hospital. They are kept in the Relief Station only long enough to permit their safe removal elsewhere for further treatment. Thus many patients die from their injuries after they leave here. Such deaths do not appear on our records at all.

From these facts, it can be seen that the number of those who are injured while under the influence of alcohol, and who die because of their injuries, is much larger than our records would show. From the records, however, we can say that 40.6% of those adults who died here from accidents during the past four years were distinctly alcoholic at the time of the injury.

ACIDOSIS IN CHILDREN.*

BY ARTHUR A. HOWARD, M.D., BOSTON.

Clinical Instructor, Harvard Medical School; Physician-in-Chief, Children's Department, Boston Dispensary.

THE literature credits Nauyn as being the first to clearly describe the condition of acidosis as

* Read at a meeting of the New England Pediatric Society, held January 29, 1915.

being the result of the pathological production of acids in the course of metabolism.

Pfaundler and Schlossman credit Giliberti with the term recurrent vomiting.

The earliest reported case of recurrent vomiting was made by Dr. Cuicere in 1841.

Dr. Gee of London in 1882 contributed the first paper in English on the subject, reporting nine cases. Von Jaksch in 1883 is said to have been the first to demonstrate acid substances of the acetone series in the urine (in diabetic urines). Recent literature by writers of various nationalities abounds in articles on the subject of recurrent vomiting.

In the literature and pediatric text-books the attention given the subject of acidosis is confined largely to a consideration of recurrent or cyclic vomiting. A great deal is said, with wide differences of opinion, about the possible etiology, but the practical clinical aspect of acidosis it seems to me has not received the attention which it deserves.

The number of infants and children coming under my observation in which acidosis has been accompanied by severe clinical symptoms has impressed me more and more strongly with the seriousness of this condition, and the practical importance of its recognition and treatment. I wish to distinguish this type of case from the cases giving a test for acetone without clinical symptoms so frequently met with in febrile conditions. In the last two years I have seen 64 cases of acidosis. Of the last 171 consecutive patients seen, ranging in age from one day to twelve years, irrespective of the reason of the visit, 31 have had a definite acidosis. These cases include only cases in which there was marked clinical evidence, as well as an acetone odor to the breath, and a positive test for acetone in the urine.

Sex did not seem to play an important part in this series. Of the 64 cases, 30 were male and 34 were female.

As regards age, my experience has differed from most writers in that the cases seen under two years have been about as frequent as those seen over that age. Of the last 31 cases 20 were among 103 babies under two years, 11 being among 68 children from two to twelve years. The youngest cases seen were a baby four days and 2 babies five days to one week. The oldest cases were a boy ten years and a girl twelve years. Some of the cases seen with a first attack when less than two years old, have been seen with a subsequent attack at an older age. Classified by attacks instead of cases, there is a more definite predominance in favor of the age above two years.

As regards environment, my impression is that although acidosis is more common among children living in good circumstances, it is far from being confined to that class.

Again, as regards temperament, rheumatic tendencies, etc., although many of the cases have been in families or children of a nervous type, or

showing at some time evidences of the rheumatic cardiac, choreic tendency, there have been many exceptions.

The next point which I wish to make is, that while it has been my experience that acetone acidosis in childhood is of frequent occurrence, the common clinical type met with is what might be called a complicating acidosis with obvious predisposing factors. While the recurrent vomiting of the text-books, as distinguished by absence of obvious predisposing or causative factors, is extremely rare if, indeed, it exists. Of the 64 cases in this series, but one case had attacks except as the result of demonstrable complicating or predisposing causes. That the one case which failed to show clinical evidence of these causes had, nevertheless, sufficiently definite predisposing etiological factors, is very clearly shown from the following brief summary of the cases.

L. Female of 6 years. Past history: full term, no feeding troubles. Severe intestinal indigestion at 3 years. Measles at 4 years. Seen August 2, 1913. Perfectly well until 3 days previous had loss of appetite, nausea, vomiting without change in diet or obvious illness. Bowels had moved daily. The child showed an acetone breath and acetone, plus diacetic acid in the urine. Had similar attack in December, 1912; June, 1913; July, 1913. Vomiting not present each time but "peculiar breath" and distaste for food. Confined to bed each time from 3 to 5 days. Diet: Unusually good; mother very intelligent and extremely careful in regulating life of patient, who was an only child. Child made good recovery and August 5 child seemed perfectly well. August 15 child had another attack. This attack similar to previous attacks and ran the same course until August 17; child had slight temperature, increasing gradually to 102. Previously normal to 100. Also very slight muscular spasm over appendix region. Child operated on that night. Operation disclosed two enlarged mesenteric nodules with band of adhesions compressing ileum to 1/3 calibre just above cecum and causing slight torsion of the ileum. Nodules removed, adhesions broken up and appendix removed. Pathological report stated mild catarrhal appendix, with no evidence of previous involvement. Mesenteric glands tubercular. Child made good convalescence. Has had splendid health and no subsequent attacks since operation 18 months ago.

The essential features of this case are strikingly similar to the case reported by Dr. W. S. Parker at the last meeting of this society, Dr. Parker's patient being a supposed recurrent vomiter, which Roentgen rays and bismuth meal and operation showed had stasis and general visceral ptosis. It is significant in this connection, it seems to me, that the various writers on the subject of recurrent vomiting differ so widely in their theories as to the etiological factors. Is it not possible that this diversity of opinion suggests a diversity of, let us say, predisposing etiological factors?

My own experience and a consideration of the literature leads me to believe that recurrent

vomiting without demonstrable cause is sufficiently unusual to indicate an extremely careful study of apparent cases for various possible predisposing causes.

It has seemed to me evident that there are many pathological conditions which are capable of precipitating an attack of acidosis.

Acute infections have been the most frequent complicating conditions in the acidosis cases coming under my observation. The site and apparent severity of the infection has not seemed to be of consequence in the production of, or severity of the acidosis. Tonsillitis, coryza, bronchitis, otitis media and infectious diarrhea have in the order named been the most frequent infections preceding an acidosis. Among other conditions noted have been intestinal stasis, intestinal intoxication, diarrhea, burns, difficult teething and acidosis following etherization and operation.

In some cases, as the result of the disease that preceded the acidosis, the child was apparently but mildly ill, with little or no elevation of temperature; in other instances severely ill with a temperature of moderate or severe degree. The acidosis that developed was as likely to be as severe in one case as in the other, mild in both instances, or develop in the case of the severe illness after the temperature had subsided and the patient was apparently convalescent.

That more than one factor may combine in causing an acidosis is suggested from the fact that a child known to be subject to acidosis may have an attack brought on by a cold when he is constipated. The same child may escape an attack repeatedly when suffering from a cold alone or when constipated and having no infection. Again, a baby having difficulty in teething over some little period, with more or less accompanying digestive disturbance, may escape an acidosis until he has an acute infection or becomes constipated. A child having a tonsillitis may recover from the attack, having a definite period of quiescence, have tonsillectomy performed and suddenly develop a severe acidosis. In other instances I believe that a moderate acidosis existing before operation is overlooked, and bad results in the way of collapse, etc., are encountered because of the presence of the acidosis.

Constipation has been the rule in a majority of the cases, the usual story being that the child's bowels had been regular until a day or two previous to the onset of the acidosis they became costive. That the constipation is not the only factor is indicated from the fact that the same child may have other attacks of constipation more marked than the one accompanying the acidosis, without an attack. Also some of the cases in this series developed an acidosis during the course or at the onset of a diarrhea or infectious diarrhea.

Certain children are apparently predisposed to acidosis, having repeated attacks from what are clinically slight predisposing causes. Of the 64 cases, 22 either have been seen in more than

one attack or give a definite history of repeated attacks.

That this predisposition is but a part of the story, however, seems evident from the fact that these patients often escape an acidosis when ill with the same disease that at other times has accompanied an active attack.

Again, of the 42 cases seen in one attack showing that they are capable of having an acidosis, not only do they fail to give a history of previous attacks, but some have been under observation for from one to five years without acidosis accompanying various infections and digestive upsets.

It would seem that the clinical evidence favored the view that these different conditions were capable of acting as predisposing factors to an upset in metabolism other than indigestion.

The clinical picture presented by this series of cases has shown marked variations as regards the onset, progress, severity and manifestations of the attack.

The usual development of the acidosis is a progressive one, with marked variations in the rapidity of the appearance and duration of the symptoms.

There are usually slight premonitory signs, such as loss of appetite, restlessness, irritability, or, if the child has been apparently convalescent from the accompanying disease, it seems suddenly not quite as well. Progressively, the mouth and lips become dry and slightly red-denied, there is abnormal thirst, increased excitability, an acetone odor to the breath, acetone in the urine, the respiration becomes more rapid and the child may have nausea to the extent of a positive distaste for food or violent vomiting may suddenly develop at this time or may be the first definite manifestation.

As the acidosis increases the patient changes from its irritable, excitable or hysterical condition and becomes listless, drowsy and apathetic. The slightly flushed face assumes an anxious appearance and the eyes look sunken; when disturbed the child is fretty and irritable, but soon drops off to sleep again, becomes more dull and hard to arouse, and then becomes unconscious. During this period the breathing becomes more rapid, shallow and irregular. The child sighs frequently, and the irregularity of the breathing may be of the Cheyne-Stokes type. In very severe or fatal cases the coma becomes deep, the breathing more irregular and shallow, the cyanosis more marked and the pulse, which has been moderately slow, quickens in rate and becomes of poor quality.

In 51 of the 64 cases vomiting was a symptom of greater or less severity. Of the 13 instances in which vomiting did not appear, treatment was begun at the first indications of nausea or as soon as the acetone odor to the breath and acetoneuria were noted, accompanied by increasing irritability, rapid respiration, etc. In some cases where vomiting was present as an early manifestation, it ceased after

the acidosis more fully developed. In other instances vomiting did not occur until late in the course of the attack, when the patient showed marked intoxication. Certainly in a majority of cases, however, the vomiting not only developed early but was most marked in the early stages of the acidosis.

The severity of the acidosis apparently varies considerably in the same patients in different attacks. Also it seems evident that certain children are more likely to have violent symptoms and a protracted course with each attack than is the course with other children.

The signs and symptoms of the accompanying diseases tend still further to vary and complicate the clinical picture in these acidosis cases. The most difficult interpretations to make that I have encountered have been to differentiate between the prostration and apathy of an intestinal intoxication or the toxicity produced by an acute infection, in contradiction to the apathy and unconsciousness of an acidosis when both conditions are present at the same time. For example: A girl of two years, giving a story of vomiting once or twice during the first day of illness became increasingly dull. She was seen on the fourth day in a semi-conscious condition with considerable prostration. Acetone breath and acetone urine were noted. The stools from the first had been rather frequent, green in color, with some mucus following cathartic. Soda bicarbonate and glucose solution were given, with child showing complete return to consciousness in 24 hours. Prostration and general condition did not show any marked improvement. Second day after the child's mental condition had cleared, blood and pus appeared in the stools and the child ran a fairly severe course of infectious diarrhea.

I wish to emphasize in this connection the importance of the early recognition and treatment of acidosis on the basis of its being a serious complication. In nearly every case of acidosis seen in consultation, where the acidosis had not been noted, the reason for the consultation was that the child seemed more ill than the physical signs of the recognized disease warranted. An untreated acidosis accompanying a mild illness is likely to produce a pretty sick and uncomfortable patient, with the results of treatment of the recognized disease far from satisfactory. An untreated acidosis or one that is well developed before treatment is begun may, I feel sure, in a severe illness be the real cause of a fatal outcome.

Among the 64 cases considered there were 3 fatalities. Two of the three were from clinical evidence not justified by the illness uncomplicated by acidosis. The third case, a moderately sick pneumonia in a girl of three years, which involved but one side of the chest, developed an acidosis on the fourth or fifth day after the onset of the pneumonia. The acidosis was untreated for at least 36 hours. Had the acidosis been recognized and treated it would seem that

the child might have successfully coped with the pneumonia.

From the standpoint of getting results in the treatment of a disease, as well as the more serious consideration of the added danger, the recognition of a complicating acidosis warrants prompt attention and adequate treatment. Even if the symptoms accompanying the presence of an acetone breath and acetone urine are extremely mild, and regardless of whether or not acetone is normally present in the urine in small quantities or is frequently present in febrile conditions without clinical symptoms, it seems to me that treatment is indicated; first, because we do not know how suddenly severe and serious symptoms may develop, and, secondly, because the early treatment is much more simple and effective.

Because of the bad results frequently encountered following etherization and operation when acetone is present, acidosis is of special practical importance to those performing even minor surgical operations.

It is beyond the scope of this paper and the knowledge of the writer to enter into questions of the actual production of acidosis or consider what members of the acetone group are most active in the production of the intoxication, or speak of the possible part played by carbon dioxide in the production of the symptom complex of acidosis. These are problems that deserve active consideration and investigation, as a better knowledge along biological-chemical lines should prove of value in directing treatment and instituting prophylactic measures. From a purely clinical point of view it seems probable that acidosis is a definite result of faulty metabolism, induced by numerous predisposing etiological factors, acting singly or collectively.

The treatment of acidosis in the absence of more accurate knowledge, should be directed toward neutralizing the acid intoxication, alleviating its symptoms, and removing, as far as possible, predisposing conditions. The patient should be placed in bed and kept as quiet and free from excitement as possible, the intestines should be promptly and thoroughly emptied. Even in the absence of vomiting, it seems a rational proceeding to stop all food, including water, until medication has been continued for a few hours. If vomiting is present even liquids, except in extremely small quantities, should be withheld until it stops. The combined use of soda bicarbonate and glucose has in my experience been more effective than the bicarbonate alone. If the acidosis is at all severe the first doses of soda should be fairly large and given at frequent intervals. A convenient plan is to give the soda every two hours, alternating with glucose. The medication is to my mind much more effective when given by mouth. The fact that the child is retaining nothing—even water being regurgitated at once—does not indicate that the medication cannot, in the majority of cases, be successfully given by mouth. If abso-

lutely nothing is given by mouth for a few hours except teaspoon doses of the prescribed medicine, the child experiences difficulty and a rapidly declining inclination to regurgitate the medicine. In many cases one, two or no doses are lost. After medication has been given successfully two or three times the child will usually retain water in teaspoon doses or be able to suck cracked ice without vomiting. Food should be started with caution, both as regards quantity and composition. I have found a barley lactose solution a convenient stepping-stone for both babies and older children. Fair amounts of carbohydrate, moderate proteids with gradual introduction of fats, have proved satisfactory in increasing the diet of the babies and older children.

As a prophylactic measure in children with repeated attacks of acidosis, I have secured good results by having the mothers start acidosis treatment, including cathartic, soda bicarbonate and light carbohydrate diet, at the first indication of the onset of any illness. In some instances even with this treatment, the child has developed mild evidences of acidosis, but in no case a severe attack, the vomiting being either entirely avoided or very mild in character and of short duration.

The principal points which I wish to emphasize as a summary are:—

1. That acidosis in children is of frequent occurrence.
2. That recurrent or cyclic vomiting, as distinguished by absence of predisposing factors is extremely rare. Cases apparently of this type should be subjected to careful study for possible concealed pathological conditions.
3. That the common clinical type of acidosis is what might be termed a complicating acidosis with predisposing factors.
4. That clinically there are numerous conditions which seem capable of acting as predisposing etiological factors in the production of an acidosis.
5. That acidosis should be considered a serious condition.
6. That the early recognition and treatment of acidosis is of practical clinical importance.
7. That prophylactic measures are indicated and practical.
8. That a more thorough understanding of the biological-chemical processes producing acidosis should prove of real value in the scientific treatment of the disease—which should be considered of definite clinical importance to both general practitioner and pediatrician—acidosis in children.

THE PARENTERAL ADMINISTRATION OF HORSE SERUM IN CASES OF HORSE ASTHMA.*

BY J. L. GOODALE, M.D., BOSTON.

IN January, 1914, I reported a series of cases of horse asthma and horse fever, and described the local skin manifestations occasioned by the application of horse serum to a scratch. Since then additional cases have come under observation, which have confirmed the previous results with reference to skin reaction. In the following paper I wish to describe some attempts to effect a resistance in such patients to the neighborhood of horses by the parenteral administration of horse serum.

The results obtained in conditions of proteidization to other proteids have been so encouraging as to suggest the probability of their attainment in these instances of horse fever and horse asthma. It remains, however, to be determined whether the internal administration is practicable, or whether the serum is best administered subcutaneously. In two cases an attempt was made to immunize the patient against horses.

CASE 1. The results obtained in this case are merely placed on record without attempting to draw conclusions, as the evidence appears to be inconclusive. The previous history of this case appears in my paper "Studies Regarding Anaphylactic Reactions Occurring in Horse Asthma and Allied Conditions" as Case 2. The essential points are here reproduced: "Mrs. B., 30 years old. For ten years the neighborhood of horses has produced sneezing, more severely of late, and accompanied by a sense of constriction in the chest. The general health is otherwise good. Horse serum applied to a scratch on the skin produced in six minutes considerable reddening and edema without the marginal white line of the preceding case. In the nose the serum gave no result. On the following morning the skin test was repeated with the same serum, without exciting any local reaction whatever."

The patient was then given one-tenth of one per cent. solution of horse serum to spray into the throat once daily, increasing at the end of two weeks to a one per cent. solution. The spray produced little or no subjective discomfort, at least no symptoms beyond occasional difficulty in breathing were noticed. Six months later the patient reported, saying that she had used the spray about a month, and that she felt considerable increase in her resistance when in the neighborhood of horses. A test of the serum on the skin produced no re-

action. The evidence seems to me here too scanty to justify conclusions.

CASE 2. Miss W. Reported in the same paper as Case 1. Essential data here reproduced. Twenty-eight years old. Asthma more or less constant throughout year, increased in the neighborhood of horses. "Has been under observation for six years. A large cystic right middle turbinate was removed in 1909 without influence on asthma. Tonsils were removed for septic detritus four years ago. During past two years asthma has been much less troublesome, and she is able to drive behind horses, although the air of stable excites an attack."

The skin test gave a marked reaction. Attempts to accomplish an increase in resistance by spraying a ten per cent. dilution of horse serum had to be given up, owing to the supervention of severe asthma, but on resuming the serum spray in dilution of one to a thousand, it was possible to effect apparently an increased resistance, both to the neighborhood of horses, and to the reactions occasioned on the skin by the serum. Six months later the patient was again examined, as her asthma had become more severe, both in the neighborhood of horses, and also at other times without assignable cause.

The patient was again tested on the skin, and showed a highly developed degree of sensitization. The horse serum, obtained from the Massachusetts State Board of Health, in the form of diphtheria antitoxin, showed in 50% dilution, an edema of over one inch in transverse diameter, with hyperemia nearly encircling the arm, and accompanied by intense itching.

It was decided now to inject the serum subcutaneously, and tests were consequently made, with varying dilutions of serum. Numerous tests were made to determine the best preservative and diluent. Alcohol in fifteen per cent. dilution proved thoroughly efficacious, preserving the antitoxine from decomposition without precipitation of the albumin. It is interesting here to note that this alcohol concentration corresponds to that which can be attained by the development of saccharomyces in a sugar solution. Different dilutions were, therefore, prepared with alcohol in water, ranging from a one per cent. to a one in ten thousand, in all of them the alcohol being present in the preparation of fifteen parts by volume.

When these solutions were applied to scratches on the skin of the arm, a 1/100% dilution produced a slightly raised white area of edema about 1/8 inch in width; a 1/10% dilution showed edema one-half inch broad, with a narrow margin of hyperemia; these not being accompanied with itching; a 1% dilution showed extensive edema, marked hyperemia and itching. The patient was first injected two days later, Nov. 12, with ten minims of 1 to 10,000 dilution of serum. Nov. 14 the patient received 10 minims of 1 to 1000, and every two or three days serum in increasing doses. On the 20th, 4 minims in a 1% dilution were given. The skin reaction at this time showed a small moderate reaction, with a 1% dilution. Nov. 30 two minims of a 50% solution produced a moderate edema of the skin, without hyperemia or itching. The strength of the injections was increased until on the 11th she received 4 minims of a 50% dilution. At this time this dilution of serum caused slight hyperemia, and an edema of less than one-half inch in diameter.

The injections caused no discomfort or subjective sensations, but were followed in the course of two

* Read at a meeting of the New England Pediatric Society, held January 29, 1915.

¹ *Annals of Otolaryngology, Rhinology and Laryngology*, June, 1914.

hours by considerable firm, deep-seated edema in the vicinity, nearly embracing the arm, persisting for six or eight hours longer. The injections have been continued at weekly intervals for a period of two months (at the time of writing), each injection consisting of 10 minims or a 50% dilution of serum. Following each injection in the upper arm, a moderate edema appears immediately, increasing in the course of three or four hours, and causing an enlargement of the arm to about twice its normal circumference. The swelling is firm, elastic, without pain, tenderness, itching or hyperemia of the skin, and disappears in six or eight hours. During the last month, the size of this swelling has diminished slowly and progressively, from an original size of approximately a hen's egg, to now a size of a pigeon's egg. The introduction of horse serum into the nose causes no discomfort or vasomotor symptoms, which were so marked originally a year ago.

The patient's statements regarding horses are to the effect that she has no asthma when in their neighborhood, but that close proximity causes sneezing. Attention should in this connection be drawn to the fact that horse fever, *i.e.* sneezing, etc., caused by horses, may not show an anaphylactic skin reaction from the application of horse serum.

Summary. Consideration of the objective phenomena shows that this case with a high initial sensitization to horse serum has acquired in the course of thirty injections of progressively increasing doses of serum a determinable increase in resistance. This resistance is characterized by failure of the serum to excite hyperemia and itching when applied to the mucous membranes or to a scratch of the skin, although edema can still be produced by hypodermic injection.

Clinical Department.

GANGRENOUS EPIPLOIC APPENDIX.

REPORT OF A CASE.

By A. R. KIMPTON, M.D., BOSTON.

THE object of the following case report is to call attention to one more condition that may be encountered when operating for what is thought to be acute appendicitis. Not uncommonly patients have been operated upon for what appeared to be appendicitis, the appendix removed, and nothing further abnormal has been found in the abdomen. The pathologist returns a report of a normal appendix, and the surgeon frequently feels that something has been overlooked.

A man forty-two years of age was seen by myself at midnight for acute abdominal symptoms. For thirty hours he had been having pain in the lower right quadrant, which had been increasing. For the past four or five hours he had been having hot fomentations, with but slight relief. When seen by myself the patient had a great deal of nausea, almost to the point of vomiting. He had had one or two similar attacks which had been of very short duration. Bowels had been regular.

The physical examination showed the patient to be very obese. The heart and lungs were negative, temperature was 98.8, and pulse was 80. The lower right quadrant showed moderate rigidity and spasm with very marked point tenderness. With increasing symptoms it seemed advisable to remove the patient to a hospital and to operate.

A right rectus incision was made through a very fat abdominal wall. There was no free fluid in the abdomen, and no evidence of fat necrosis except the following: Upon examination of the region of the appendix an almost black appendage of fat presented itself. This was an epiploic appendix, which had apparently twisted upon itself. This was tied off and removed. The appendix itself was perfectly normal in appearance and was, likewise, removed. Exploration showed nothing further abnormal. The abdomen was closed in layers without drainage, and the patient had an uneventful convalescence with the exception of an ether bronchitis and some breaking down of the superficial fat in the abdominal wall.

The pathological report by Dr. Mallory was "Normal appendix. Fat tissue received was hemorrhagic and necrotic."

To me this condition, simulating appendicitis, was new, but I now know of two similar cases operated upon by other surgeons, and Dr. Mallory tells me that he has seen this condition at autopsies several times. Not uncommonly we find tabs of calcified fat, as well as pieces of calcified fat, free in the abdominal cavity which, perhaps, originated as did the condition in the above case.

This patient had every local symptom of an acute appendix and was operated upon with the expectation of finding this condition. This shows that under similar circumstances one would do well to bear in mind this possibility.

I have been unable to find reports of any such condition in medical literature.

Reports of Societies

NEW ENGLAND PEDIATRIC SOCIETY.

RICHARD M. SMITH, SECRETARY.

The meeting of Jan. 29, 1915, was held at the Boston Medical Library, the president, Dr. E. M. BUCKINGHAM, of Boston, in the chair.

The following papers were read:

ACIDOSIS IN CHILDREN.¹

By ARTHUR A. HOWARD, M.D., Boston.

PARENTERAL IMMUNIZATION IN CONDITIONS OF PROTEID SENSITIZATION.²

By J. L. GOODALE, M.D., Boston.

WEANING—ITS RELATION TO ANAPHYLAXIS AS SHOWN BY DIFFERENTIAL BLOOD COUNTS.

By H. C. BERGER, M.D., Boston.

¹ See JOURNAL, page 747.

² See JOURNAL, page 751.

DISCUSSION.

Dr. R. S. EUSTIS: Dr. Howard's paper. Dr. Smith has given me the privilege of examining and reporting on a number of urines which he has obtained during the past month, the total number being about thirty. No less than twenty of these showed a slight trace of acetone. These specimens were taken at random from patients who had no sign of infectious disease, any cold, digestive upset or sore throat. Of especial interest were the evidences of infectious character. There were three children in one family that came down, one after the other, with digestive disturbances, and each one of these showed a moderate amount of acetone in the urine. There was another instance of two children in one family at the same time; still another case where an older child has a history of recurrent vomiting, the patient merely becoming out of sorts and cranky. The mother told Dr. Smith that if it had been the older child she would have started soda bicarbonate several days prior to the visit; as it was she waited, and we took some of the urine and found acetone. Of these twenty acetone cases, certainly not over four could be classed in any way as recurrent vomiting, or were of an exceptionally severe type. There were ten which could be grouped roughly as digestive disturbances. There were several colds and two or three cases of tonsillitis. The whole thing was very interesting, as showing the frequency of acetone in the urine, during this winter, anyway.

Dr. J. L. MORSE: It seems to me that this whole question of so-called acidosis in recurrent vomiting is a very vexed one. My own impression is that the tendency in the last one or two years is to exaggerate the importance of the presence of the acetone bodies in the urine. My experience is that the acetone bodies are very commonly present in the urine of children and babies that are sick for any reason and that in the vast majority of instances the presence of these acetone bodies is of no pathological significance. We must remember that we are bound to find the acetone bodies in the urine whenever a child is starved, or even when it is partially starved. We must also remember that if there is a disturbance of the carbohydrate metabolism we are almost certain to get the acetone bodies in the urine. My experience leads me to feel that we can disregard the presence of acetone bodies in the urine unless there are other symptoms which show evidences of acid intoxication. That is, my experience has led me to an entirely different conclusion from what Dr. Howard's has led him. Recurrent vomiting I look on not as a disease but as a symptom-complex which may be due to a variety of conditions. One of the causes of recurrent vomiting I feel very positive is acid intoxication, and the reason that I feel so is that I have seen cases in which the acetone bodies were present in large amounts at the very onset of the disease. The finding of acetone bodies in the urine after a child has been vomiting for twenty-four hours does not show in any way that the acetone bodies are the cause of the attack of vomiting. I feel equally positive that other attacks of recurrent vomiting are due to other disturbance of metabolism. Sedgwick has shown that they are due to the disturbance of the creatinin metabolism, and Snow, of Buffalo, has shown fairly definitely that some are due to an excess of uric acid. I agree thoroughly with Dr. Howard that true recurrent vomiting is a rather unusual condition, and I see a

great many cases called recurrent vomiting which seem to me to be cases merely of recurrent indigestion. Why we should have these attacks of recurrent vomiting in certain children as the result of acid intoxication is a very obscure problem. The best explanation which I have seen is, I think, that given by Salge in the *Jahrb. f. Kinderheilkunde*, about a year ago, in which he, in view of his experience, came to the conclusion that they were due primarily to a disturbance of carbohydrate metabolism, but only occurred in children of a definitely nervous make-up, and not in the average child. I think that I was one of the earliest to advocate the use of bicarbonate of soda in the treatment of recurrent vomiting, but as I have seen bicarbonate of soda used in these cases I am not sure but what a good many of them have done as well with the older treatment advocated twenty years ago by Dr. Rotch with bromide and chloral by enema. I do not want to minimize acidosis, but I do feel that its importance is being exaggerated at present.

Dr. J. L. MORSE (replying to Dr. Porter): I do not know that I can tell exactly as to the effect of fatigue in these cases, but my experience has been in these cases of recurrent vomiting that if you got at any etiological factor at all it is much more likely to be over-exertion or over-fatigue than it is indiscretion in diet.

Dr. H. T. HANDY: I would like to ask the reader how long the recurrent vomiting lasts, if a child is supposed to outgrow it, or if there is any definite age after which it does not have it?

Dr. HOWARD, closing: In answer to Dr. Handy's question as to the age when the acidosis attacks may cease to appear. It has been my experience that the condition becomes less frequent after five years and quite rare after 10 years.

In regard to the remarks of Dr. Morse to the effect that the importance of acidosis is being over-emphasized and that most cases showing acetone breath and acetone in the urine are not serious; I doubt if there is any real difference of opinion. It has also been my experience that acetone is very frequently present without doing any particular harm. The type of case referred to in this paper, however, has shown definite and serious clinical manifestations and the condition has apparently warranted real concern. I feel that this more serious type of acidosis is of sufficiently frequent occurrence and seriousness to justify prompt consideration and treatment.

Dr. E. H. PLACE: This is a most valuable paper and rich in suggestion of the possibility of specific curative treatment of these conditions which have so long been resistant to beneficial management.

The value is great also of being able simply and easily to find out the specific pollens or other proteins causing these reactions. I was struck by the experience of the patient quoted by Dr. Goodale of being so sensitive to horse protein as to suffer attacks from being near hair mattresses. It suggests the old fairy tale about the princess who could feel a pea under seven feather beds might not be so ridiculous.

Seriously, it is marvellous how small an amount of the protein will bring on attacks. It is well known that in guinea pigs what infinitesimal doses will sensitize, but much larger doses are usually necessary to bring on a marked and fatal reaction. It is possible that the application of the intoxicating protein directly to the mucous membranes of the respiratory tract would cause reactions of this

type more readily than if the protein were injected under the skin, on account of local sensitization. Tissues may be sensitized locally under certain conditions without the whole body being so sensitized.

Dr. Goodale spoke of one of his patients being so benefited that she could ride behind her *favorite horse* without an attack. I should like to ask if the suggestion contained therein were true that this patient reacted more to some horses than to others?

We frequently notice of course in giving horse serum antitoxin for diphtheria, that the serum of some horses is worse than others in causing severe reactions.

I should like to ask if in any of this series of cases Dr. Goodale tried the cattle serum to see if any cases ever spontaneously reacted?

DR. GOODALE, in closing. I have not used any other horse serum than that supplied by the Massachusetts State Board of Health. Three lots were sent me at different times, and I can see no difference in the amount of the reaction caused, but it was not possible to make definite comparative tests. Wiedemann suggests the use of ox serum. He employed it in a case of diphtheria, which had previously received an immunizing dose of antitoxin. Fearing anaphylactic shock, he gave the child a drop of ordinary antitoxin from the horse with very nearly fatal result. He then tried giving it by mouth, but after 24 hours there appeared a delayed shock. He then injected ox serum antitoxin and the child was promptly relieved. It is said to be impossible to immunize an ox against diphtheria to the same degree of potency as the horse, but it is suggested that all Boards of Health have ox serum on hand in readiness for such emergencies.

WEANING—ITS RELATION TO ANAPHYLAXIS AS SHOWN BY DIFFERENTIAL BLOOD COUNTS.

An abstract of the paper read by Dr. H. C. BERGER of Boston.

At the suggestion of Dr. Fritz B. Talbot, following the work of Herrick, Johns, Schwenker and Schlert, Weinberg and Sequin and Schloss, on relation of eosinophilia to anaphylaxis, differential blood counts were made on weaning babies at the Massachusetts General Hospital and St. Mary's Infant Asylum.

Breast fed babies were given daily feedings of cow's milk, and babies previously on a modification of cow's milk were given sheep's milk, egg albumen water, or barley water. In practically all cases there was a marked increase in the percentage of eosinophiles present. The highest percentage usually appeared on or about the tenth day, and then rapidly returned to normal.

Babies fed on animal proteids showed a more marked increase in eosinophiles than those fed on a vegetable proteid.

DISCUSSION.

DR. R. C. LARRABEE: The results of Dr. Berger's blood counts must be interpreted with some caution, as the total number of cells enumerated in each case was apparently small. Normally the eosinophiles constitute about one per cent. of the leucocytes. In a differential count of 100 cells this would mean that only one eosinophile would be seen. Obviously a five-fold increase would be within the limits of possible chance variation between different counts

from the same smear. At least a thousand leucocytes should be counted in each case. If slight variations are to be considered, the number should be higher—perhaps even 10,000—a long, tedious undertaking. Moreover, what we want to know is the *number* of eosinophiles per cu. mm., not their percentage relationship to other cells. Hence we should have, besides differential counts, an enumeration of the total number of leucocytes per cu. mm.—an ordinary "white count." Otherwise we can not say that a rise in the percentage of eosinophiles is not due to a fall in the other cells. In spite of these criticisms it must be admitted that the uniformity and suggestiveness of the reader's results are evidence of the correctness of his technique.

DR. J. L. MORSE: I would like to ask the reader if he has made any consecutive examinations of the blood in babies that had been taking the same food, whether it was breast milk or an artificial food, as controls?

DR. E. H. PLACE: I understand that in most of these experiments the foreign protein was given once daily from the beginning and throughout; while in a few, single doses were given. Under both these conditions the eosinophilia occurred. It would seem from our knowledge of allergy in anaphylaxis that the reaction was simply a reaction due to the protein and that there was no evidence that sensitization occurred. In guinea pigs if the foreign protein is given daily, it indefinitely postpones the development of sensitization. The time of appearance of the eosinophilia being the same in these cases whether one dose or repeated doses, would suggest that eosinophilia has no relation to sensitization.

DR. BERGER, in closing: In all these cases not over 150 cells were counted, and in none less than 100 cells. I counted 150 cells in a good many normal children outside of this series and I never found an eosinophilia above 4%. I selected children with no skin diseases and in which there was no reason to suspect an eosinophilia. Dr. Schloss, some years ago, investigated a tremendous series of infants and counted a much higher number than 150 cells. He decided that anything above 5% would certainly be abnormal, but I think from some of his work since then that he would probably now put it somewhat lower than that. The way that these counts were made is that each day the infants were brought into the examining room in different order. The number was taken and the date put down on the slide and the slides were all counted, so that it was a mechanical procedure. I had no idea as to whose slide was being counted, or as to the length of time since the foreign proteid was started, and it was only after all the counts were made that the results were classified. After giving a foreign protein there is a definite period when sensitization increases. This is almost always on or about the tenth day. That is when the eosinophilic count is at its highest, that is probably when the climax of the sensitization has been reached, and from that point on the eosinophilia comes down and apparently the child is immunized. That is, he reaches the highest point of sensitization at or about the tenth day, if we can take the results of the work referred to earlier in the paper as a proper interpretation of the eosinophilia in our cases.

Replying to Dr. Morse's question; I have never run a series of controls on any one such infant.

Book Reviews.

Infant Feeding. Its Principles and Practice. By F. L. WACHENHEIM, M.D., Attending Physician Sydenham Hospital and Mount Sinai Dispensary, New York City. Philadelphia and New York: Lea and Febiger. 1915.

The author states in his preface that "this manual is designed to supply the practitioner with a reference handbook, of moderate size, in which he may find an exposition of the present theory and practice of infant feeding. The material here presented can be secured only by reading a vast journalistic literature which is extremely conflicting in its statements and of little practical use without extensive sifting."

The author's summary of the peculiarities of digestion and metabolism in infancy is fairly complete and up to date. His point of view is, in general, very reasonable. He comes out strongly in favor of breast-feeding and shows the objections to the use of undiluted cows' milk. He is not fair in his criticisms of percentage feeding, which he calls Rotch's method. He apparently fails to realize that the feeding tables which he quotes were prepared years ago, before our knowledge of the digestion and metabolism of infancy was as complete as it now is, and that no intelligent believer in percentage feeding follows any table or believes in any set "method" of feeding. Feeding in percentages is merely a method of calculation and a means of fitting food to the digestive capacity of the individual infant. It is not a system of feeding. After criticising other "methods" of feeding, the author gives a table of his own, which hardly seems consistent. He classes sodium citrate among the alkalies and is apparently unaware of the work of Bosworth and Van Slyke as to its action. He is very strongly in favor of four-hour intervals. He disregards the fact that infectious diarrhea is due to a variety of organisms and that the treatment should be modified according to the etiologic organism in the given case. He gives a very comprehensive review of the literature. He criticizes everyone, Americans and Germans alike, without fear or favor. We do not agree with all his conclusions, but feel that he has intended to be fair but is mistaken. The book affords very interesting reading. We fear, however, that although it is intended for practitioners no one but a pediatricist will really appreciate it.

With Sabre and Scalpel. By JOHN ALLAN WYETH, M.D., LL.D. Illustrated. New York and London: Harper and Brothers. 1914.

This picturesque volume of personal and public reminiscence, the autobiography of a soldier,

and surgeon, is an interesting complement to the recently published personal memoirs of Dr. John H. Brinton. Brinton was a Philadelphian and served throughout the Civil War in the Northern army in important posts as brigade surgeon and field medical director. He subsequently founded the Army Medical Museum at Washington. Dr. Wyeth, on the other hand, a native of Alabama, served throughout the war in the Southern army, though in the ranks and not in a medical capacity. Studying medicine after the war, he has led an active professional life and, as founder of the New York Polyclinic, has made important contributions to the progress of post-graduate medical instruction. The vivid personal narrative of Dr. Wyeth's experiences in the war and throughout his active and varied life, present an admirably contrasted picture to that drawn by Dr. Brinton of his experiences in the opposing army. It is chiefly for their contemporary record of the conditions prevailing on both sides of this great conflict that these two autobiographic volumes are of interest and value, not merely to physicians but to students of history. Not the least delightful part of Dr. Wyeth's volume is some of the verses printed at its close, especially the lines to his mother and the translation of Heine's verses to a flower.

The Cancer Problem. By WILLIAM SEAMAN BAINBRIDGE, A.M., Sc.D., M.D. New York: The Macmillan Company. 1914.

This volume is perhaps the most elaborate historical review and critical study which has yet appeared of that greatest of remaining pathologic problems, the riddle of cancer. After a careful sketch of ancient evidences of cancer, the author reviews the history of modern cancer research and the distribution of the disease locally and ethnically. He points out some of the fallacies of statistics of cancer and reviews at length the theories of its etiology and its histopathology. Next he gives a résumé of the world's work on cancer research and recapitulates the clinical course, diagnosis, prophylaxis and treatment of the disease. The final section of the work deals with the modern campaign of education for the prevention, early diagnosis, and prompt treatment of cancer. The volume closes with an elaborate classified bibliography of several hundred titles. It is well illustrated by thirty-nine full page plates and fourteen text cuts. As a summary and critique of the present status and prospects of our knowledge of cancer, Dr. Bainbridge's delightfully well-written volume affords interesting and profitable reading, not only for physicians, but for the educated laity.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, MAY 20, 1915

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*
WALTER L. BURRAGE, M.D. } *For the Massachusetts Medical Society.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

SUBTEMPORAL DECOMPRESSION FOR THE RELIEF OF CEREBRAL SPASTIC PARALYSIS.

IN a recent paper (*American Journal of the Medical Sciences*, for April) Dr. William Sharpe of New York writes of the advantages of the operation of cranial decompression for the relief of intracranial pressure from tumors of the brain, from fractures of the skull, from brain abscess, and from spastic cerebral paralysis. In regard to the last-named he explains that naturally the cases due to a lack of development or malformation of the brain and its pyramidal tracts are not suitable for operation, but claims as rightly operable those having a history of difficult labor, with or without instruments, in which, upon ophthalmoscopic examination, definite evidences of intracranial pressure are found in the dilated retinal veins, edematous blurring and haziness of the nasal halves of the optic disks, and signs of old intracranial pressure. These, he holds, can be improved by merely a

relief of the intracranial pressure. The local pressure effects of a hemorrhage, or its resulting cystic formation, are offset by the decompression; a bilateral decompression being performed if the intracranial pressure is high. If the hemorrhagic clot or its subsequent cyst can be removed, so much the better; but in many instances this is not possible. Of course, the longer the clot and its cystic formation are allowed to exert pressure upon the cortex, the more impaired do the cortical nerve-cells become; yet, in his experience of 65 operated cases, only five of them presented the hemorrhagic cyst in or beneath the cortex—that is, the cortical cells were not primarily destroyed, but merely impaired by the pressure upon them, as was the condition in 45 cases observed at the operation. Thus, the longer the intracranial pressure is permitted to continue, the greater will be their impairment; resulting in a persistent and even increasing stiffness and spasticity and, in the majority of instances, a steady mental deterioration. Sharpe's operative mortality in the 65 cases has been six. Four of the fatal cases, however, were of extreme spastic diplegia in children under two years of age who were much emaciated and had great difficulty in breathing and swallowing; a type of case which he says should not be operated upon, as the anesthetization alone is too great a risk. In the past, in these cases of spastic paralysis, attention has been centered upon the correction of deformities and the lessening of spasticity, and the improvement following upon the procedures employed has been only temporary in all but the mild cases. In the instances operated upon by cranial decompression great improvement has as a rule been noted, and although sufficient time has not yet elapsed since the first operation (June, 1913) to permit of a definite judgment, he believes that the improvement will prove permanent.

It is a fact, however, that Sharpe's conclusions have not been generally accepted by the neurologists. This was evidenced at the medical meeting in New York, when he made the first report of his cases and presented a number of the patients he had operated on. At that time the feeling was expressed that in his surgical ardor he had permitted himself to be deceived. Thus, Leszynsky stated that the hopefulness and enthusiasm as to cure in these cases of infantile cerebral palsy were not justified by the facts, and were based upon an erroneous assumption as to

the condition in the brain. The qualification had been made that the operation was done only in those cases in which "pressure upon the brain was shown by ophthalmoscopic examination." He felt confident, however, that upon further investigation the patients exhibited would be found not to come up to the required standard, as claimed, when subjected to a critical neurological analysis. It was true that the spastic hemiplegia was the direct result of meningeal or cortical hemorrhage over the Rolandic area, but the presence of a cyst, secondary to the hemorrhage, was merely a terminal condition. The paralysis, due to damage to the pyramidal tract, followed usually by secondary degeneration, was present for some time prior to cyst formation, and it was entirely unwarranted to assume that pressure from such a cyst was an important etiological factor in the paralysis. Hence, there was no rational indication for removing a portion of the skull for the relief of supposed intracranial pressure. He recalled that about twenty years ago the Lannelongue operation was in vogue—a procedure consisting in the making of long longitudinal furrows in both parietal regions, and based on the false idea that a normal brain is prevented from proper growth and expansion on account of premature synostosis. It was abandoned, as it failed to accomplish the desired results, and it was soon conclusively demonstrated that we were dealing with a defective brain. Dr. Sharpe had decried all other forms of treatment, as being directed only to peripheral conditions, and not to the source of the trouble; but he had admitted that the desired improvement required the aid of such measures subsequent to the cranial operation. As to the alleged mental improvement, it seemed to him that this was but temporary and the result of environmental changes, and also largely a matter of self-deception on the part of the mother. A similar state of affairs had occurred at the time of the vogue of the Lannelongue operation, and this was but a repetition of history. He, therefore, felt called upon to protest against this surgical plan of treatment in these cases, as being illogical and unsupported by a sound pathological foundation.

Another speaker raised the point that Dr. Sharpe had unjustifiably made the accoucheur the scapegoat for the mental condition of such patients as he had presented; stating that if for-

ceps delivery were the cause, we certainly should have many more cases of feeble-mindedness, idiocy and spastic paralysis than was now the case. The bones of the skull "shingled" when the head passed through the pelvic outlet, and the child's brain was so pliable that it could stand moulding into a long oval during birth. Flat-head Indians made pressure with a board on their babies' heads, to produce their characteristic form, but subnormal mental conditions were not noticed among them. The trouble was that these children's brains were born defective, and no operation short of implanting a new and perfect brain could make a perfect individual.

It is to be noted that in his paper Dr. Sharpe makes the announcement that a detailed report of his cases is to be published soon, and this will be awaited with interest. Although, as he himself acknowledges, sufficient time has not elapsed to establish the permanency of the improvement, in some instances, it has now been nearly two years since the operation, and if, in these, continuous improvement shall have been observed, it would seem to afford some justification at least for the procedure, whether the view advanced of the pathology in these selected cases of spastic paralysis is correct or incorrect.

PUBLIC HEALTH LEGISLATION IN RHODE ISLAND.

THERE has recently been in Rhode Island a definite legislative attempt to promote the investigation and control of occupation diseases in that state. On April 1, Dr. John G. O'Meara of Providence presented, before the House of Representatives of the Rhode Island General Assembly, the following resolution authorizing the governor to appoint a committee to study occupation diseases and to report to the next session of the Assembly:—

"Whereas, The employment of men and women in certain occupations is known to be attended with more than ordinary danger to health, giving rise to what is known as "occupational diseases," and

"Whereas, Unnecessary sickness and shortening of life, from whatever cause, is a serious loss and of grave concern to the state and to all the people, and

"Whereas, It is believed to be possible by public education, and by enforcement of proper measures, largely to prevent unnecessary sick-

ness and premature death among employees in various trades and occupations, therefore be it

"Resolved, That the governor is hereby authorized and directed to appoint a committee of six citizens familiar with occupational diseases to make a thorough investigation of the effect of occupations upon the health of those engaged therein, with special reference to dust and dangerous chemicals and gases, to insufficient ventilation and lighting, and to such other unhygienic conditions as in the opinion of said committee may be specially injurious to health, and to report to the next general assembly the results of such investigation, with such recommendations for legislative or other remedial measures as it may deem proper and advisable, and the sum of \$500, or so much thereof as may be necessary be and the same is hereby appropriated to pay the expenses of the investigation by said committee; and the state auditor is hereby directed to draw his order or orders upon the general treasurer for the payment of the same, out of any money in the treasury not otherwise appropriated, upon the receipt of vouchers approved by the governor."

This resolution, unfortunately, was not reported from the finance committee to which it was referred, but it is expected that the subject will be renewed next year. Meantime the Assembly has passed this year a bill (House No. 348) to require the reporting of certain occupation diseases. The diseases included in this act are specified as follows in the text of the bill:—

"Section 1. Every physician in this state attending on or called in to visit a patient whom he believes to be suffering from poisoning from lead, phosphorus, arsenic, brass, wood-alcohol, mercury or their compounds, or from anthrax, or from compressed-air illness, or any other ailment or disease, contracted as a result of the nature of the patient's employment, shall within forty-eight hours of such attendance send to the state board of health a report stating:

“(a) Name, address and occupation of patient.

“(b) Name, address and business of employer.

“(c) Nature of disease.

“(d) Such other information as may be reasonably required by the state board of health.

"The reports herein required shall be on or in conformity with the standard schedule blanks hereinafter provided for. The posting of the report, within the time required, in a stamped envelope addressed to the office of the state board of health, shall be a compliance with this section.

"Sect. 2. The state board of health shall prepare and furnish, free of cost to the physicians included in Section 1, standard schedule blanks for the reports required under this act. The

form and contents of such blanks shall be determined by the state board of health.

"Sect. 3. Reports made under this act shall not be evidence of the facts therein stated in any action arising out of the disease therein reported.

"Sect. 4. It shall furthermore be the duty of the state board of health to transmit a copy of all such reports of occupational disease to the chief factory inspector."

This act will take effect on July 1, 1915. The assembly has also passed a bill (House No. 136) amending the previous act of 1912 relative to the sale of wood alcohol, providing for the conspicuous labeling of all vessels containing wood alcohol and establishing a fine or imprisonment for the sale, or possession with intent to sell, of articles containing wood alcohol not so labeled.

Another act (House No. 166) passed by the assembly prohibits the manufacture or sale of adulterated, misbranded or injurious foods or drugs. By another (House No. 201) "in order to prevent the spread of communicable diseases the state board of health is authorized to prohibit, in such public places, vehicles, or buildings as it may designate, the providing of a common drinking cup and of a common towel."

These measures, which are analogous to similar legislative acts already established in some other states, are indicative of a commendable and alert concern in public health problems in Rhode Island, and their successful passage and enforcement should lead to further progress in similar directions.

ACIDOSIS IN CHILDREN.

THE publication, in another column of this issue of the JOURNAL, of an article by Dr. Arthur A. Howard of Boston on "Acidosis in Children" recalls the epidemic of this condition which prevailed in and about Concord, N. H., in Dec., 1913, and in Jan., 1914, and which was officially reported by Dr. Carleton R. Metcalf of that city in a paper on "Acidosis with Autointoxication in Infants and Children," presented before the annual joint meeting of the New England Pediatric Society, the Philadelphia Pediatric Society, and the Pediatric Section of the New York Academy of Medicine, in New York City, on November 5, 1914, and published in the January number of the *American Journal of Diseases of Children*.

Dr. Metcalf's report was based on a study of one hundred consecutive cases occurring in apparently epidemic form. Among these there were nine fatalities. The earliest cases appeared at Penacook, five miles from Concord; other sporadic cases occurred at Boseawen and Canterbury, ten miles from Concord in either direction; but the majority were in the city itself. Indiscretions in diet preceded the onset of many of the cases, but no definite defective food supply could be determined as the cause. Many of the cases were associated with respiratory infection, and Dr. Metcalf is inclined to believe the origin infectious, though without bacteriologic proof.

Perhaps one of the most interesting subjects in connection with this epidemic is that of the history of the disease. According to Dr. Howard, Nauyn is credited in the literature as being the first to describe clearly the condition of acidosis as the result of the pathologic production of acids in the course of metabolism. Gee of London is said to have contributed the first English paper on the subject in 1882. At the time of the Concord epidemic Dr. John Lovett Morse of Boston published the following brief sketch of the bibliography of the disease, referring particularly to the elaborate work of Brackett, Stone and Low published in the *JOURNAL* in 1904.

"Litten (*Zeitschr. f. klin. Med.*, 1883-4, vol. 7, p. 81) described this condition in children in 1883. Baginsky (*Arch. f. Kinderheilkunde*, 1888, vol. 8, p. 1) made a very careful study of acetonuria in children in 1888. Czerny and Keller called especial attention to acid intoxication in the acute gastrointestinal diseases of infancy in 1897 (*Jahrb. f. Kinderheilkunde*, 1897 vol. 45, p. 274). Marfan, 1901, describes a series of cases under the head of Vomiting in Acetone-mia, which are apparently identical with the cases now under discussion (*Archives de Médecine des Enfants*, 1901, vol. 4, p. 641). Peirson of Salem, Mass. (*Archives of Pediatrics*, 1903, vol. 20, p. 505), described a series of these cases in 1903, as did Edsall, formerly of Philadelphia but now of Boston, in 1902 and 1903 (*Philadelphia Medical Journal*, 1902, vol. 9, p. 1155, and *American Journal of Medical Sciences*, 1903, vol. 125, p. 629). Brackett, Stone and Low reported a series of cases from the Boston Children's Hospital, with an extensive review of the literature, in 1904 (*BOSTON MEDICAL AND SURGICAL JOURNAL*, 1904, vol. 151, p. 2)."

Especial reference should also be made to the paper by Dr. Morse on "Acid Intoxication in Infancy and Childhood," published in the *Archives of Pediatrics* in 1905 (vol. 22, p. 561).

Dr. Howard in his article, reports a further series of 64 cases of acidosis in children, not, however, appearing in epidemic form, and among these there were three fatalities, a mortality but little more than half that of the Concord epidemic. Dr. Howard also discusses particularly the treatment of the disease and his conclusions in this respect may profitably be compared with those of Dr. Metcalf, and with those of Parke in his report of the recent Birmingham epidemic (*Jour. A. M. A.*, 1907, vol. xlix, p. 1827; and 1910, vol. lv, p. 991), in which the mortality was 71%.

Perhaps the most important point for emphasis in conjunction with a comparative study of the various contributions is that the condition of acidosis is one likely to be present with considerable constancy among children under various circumstances of illness, and liable to occur with greater virulence in epidemic form as a result of some accessory cause not yet fully understood.

THE EARLY DIAGNOSIS OF TUBERCULOSIS.

THE NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS has recently formulated plans for a movement among physicians and medical societies to secure more interest and coöperation in the anti-tuberculosis campaign in this country. The executive committee of this Association has two specific suggestions to offer in this connection. The first is that each state medical society, by a special resolution or otherwise, urge upon all of its members the importance of special training in the early diagnosis of tuberculosis. The second suggestion is that each state medical society recommend to each of its county or local societies that at least one of their meetings every year be devoted to the discussion of tuberculosis. The National Association offers its services in the furtherance of either of these suggestions.

The movement on the part of the National Tuberculosis Association is a well-timed one. A well known Boston physician recently made the statement that if one wished to clear the hall at a medical meeting, one only had to announce that the subject of tuberculosis would next be considered. At one of the most important meetings of the year, held by the Suffolk District

Medical Society, at which the State Commissioner of Health read a paper of vital importance to every doctor in this community, there was but a sparse attendance. There is a growing feeling among a large number of the members of the National Tuberculosis Association that because tuberculosis is largely a social and economic problem, social workers and not physicians should be in control of the campaign. This is an unfortunate state of affairs. While there are bound to be waves of enthusiasm among the laity and the public at large in regard to any popular campaign such as that waged against tuberculosis, which are generally followed by periods of depression and lack of public interest, this ought not to be the case in the medical profession.

Tuberculosis has been in the past, and still is, one of the greatest if not the greatest of the problems which confront us. Any disease which annually kills over 200,000 people in the United States, needs continued and aggressive action on the part of the doctors of this country. In Boston, at least, there has been no meeting of the Suffolk District Medical Society this year or last which has particularly taken up the subject of tuberculosis.

It is hoped that the efforts of the National Association to arouse further interest in tuberculosis and in the prevention of this disease, as well as in preventive medicine in general, will meet with a hearty response from the medical profession.

EXPERT ADVICE DISREGARDED.

AN example of unwise, hasty and ill-advised public health legislation occurred in the passage, by the Massachusetts House of Representatives on May 6, of Mayor Curley's so-called pure bread bill, which provides for the labeling of all loaves of bread containing any ingredients other than those commonly sold for food products. The bill is injudicious because its provisions include ingredients which have been used for several years and which are not harmful to health. The labeling provision is particularly undesirable because of the unsanitary possibilities connected therewith. In realization of these defects, Dr. Allan J. McLaughlin, state commissioner of health, prepared a substitute measure, which was offered, eliminating from the Curley bill the labeling provision and allowing

bakers to use any ingredient tending to advance the art of baking, provided it be not dangerous to the public health. This rational substitute, which would have provided for the public all needed protection, was, however, defeated for political motives and the Curley bill passed. This bill was signed by the Governor on May 15, and will become operative on June 15. In the light of this legislative action it may well be queried what is the value of expert advice if it is to be overridden by other authority without special knowledge or experience.

HEALTH CONDITIONS IN BELGIUM.

WHATEVER may be said of the international ethics involved in the invasion of Belgium, it appears that in matters hygienic the Germans are doing their full duty by the country. Dr. Mamlock, a German medical writer, describes the present health administration there in a recent number of the *Deutsche medizinische Wochenschrift*, and the *British Medical Journal* for April 3rd admits that the sanitary conditions of the country are "not totally disorganized."

The health department, ostensibly under the control of the Belgian authorities, is really run by the Germans, and the physicians of both nations are coöperating in prophylactic measures, holding joint meetings from time to time to further this work. Their chief care at present is to prevent the spread of venereal diseases, which seem to be unusually prevalent.

Namur is the headquarters for military medicine in Belgium. The Belgian Sisters of Charity and the local health department are in charge of infectious diseases. The control of the hospitals in the town has been assumed by the Germans and many convents have been converted into hospitals, x-ray apparatus, dental departments, medicinal baths and other appliances having been installed.

MEDICAL NOTES.

FINE WEATHER BRINGS LOW DEATH RATE IN NEW YORK.—There were 1609 deaths and a death rate of 14.46 reported during the last week as against 1607 deaths and a rate of 15.01 for the corresponding week of 1914, an increase of two deaths and a decrease in the rate of .55 of a

point, which is equivalent to a relative decrease of 61 deaths.

The causes showing an increased mortality were measles, scarlet fever, diarrheal diseases and lobar pneumonia.

Those showing a decreased mortality were diphtheria, whooping cough, typhoid fever, organic heart and kidney diseases, broncho-pneumonia and pulmonary tuberculosis.

Viewed from the point of age grouping, the mortality of children under five years of age was considerably above, while that of adults and old people was slightly below that of the corresponding week in 1914.

The death rate for the first nineteen weeks of 1915 was 14.71 per one thousand of the population as against a rate of 15.41 for the corresponding period of 1914, a decrease of .71 of a point.

PHYSICIANS ABOARD THE LUSITANIA.—So far as ascertained, it is known that there were five American physicians aboard the *Lusitania* when she was sunk off the Irish coast on May 7. They were Dr. Howard L. Fisher of Washington, D.C., and Dr. F. Warren Pearl of New York, a surgeon-major in the United States army during the Spanish-American War, both on their way to join the American Red Cross unit in Belgium. Dr. James T. Houghton of Troy, N.Y., Dr. O. N. Kenan of Wilmington, N.C., and Dr. D. V. Moore of Yankton, S. D., who had volunteered his services to the British War Office and was on his way to report for duty. The fact that all these physicians were saved is presumably attributable to their superior coolness and self-possession in emergency. One of the most regrettable losses was that of Madam Depage, who has recently been in America raising money for the Belgian Red Cross.

ESCAPE OF A LEPER FROM JAIL.—Report from Springfield, Ill., states that an Italian leper who for the past three months has been imprisoned in the local jail, escaped on May 6 and is still at large.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.—The second annual meeting of the American Association of Immunologists was held in Washington, D.C., on Monday, May 10, under the presidency of Dr. Gerald B. Webb of Colorado Springs. A large program of addresses was presented and Dr. Emil Abderhalden of Halle, Germany, was elected to honorary membership. A complete report of the meeting will appear in a later issue of the JOURNAL.

GERMAN ASSOCIATION OF SCIENTIFIC MEN AND PHYSICIANS.—Report from Berlin states that Dr. Friedrick von Müller, professor of internal medicine at Munich, has been elected president of the German Association of Scientific Men and Physicians to succeed the late Dr. Eberhard Fraas.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.—At the annual meeting of the Pathological Society of Philadelphia on April 22, Dr. David L. Edsall of Boston delivered the annual address on "Bearings of Industry on Medicine."

PREVALENCE OF MENINGITIS, PELLAGRA AND POLIOMYELITIS.—The weekly report of the United States Public Health Service for April 30, 1915, states that during the preceding month of March there were reported 37 cases of cerebro-spinal meningitis in Virginia, 13 each in Massachusetts and Ohio and seven each in California and Indiana. During the same month 51 cases of pellagra were reported in Virginia and 38 in South Carolina. There were 20 cases of poliomyelitis in Virginia and eight in Massachusetts.

AWARD OF THE RICKETTS PRIZE.—Report from Chicago on May 5 states that the Howard Taylor Ricketts prize has been awarded by the faculty of the University of Chicago Medical School to Dr. Maud Slye, a medical research worker for her experiments in mouse cancer.

AWARD OF OSIRIS PRIZE.—Report from Paris on May 5 states that the French Institute has recently divided the accumulated funds of the Osiris prize, of which no award was made in 1912, to Drs. Chantemesse, Widai and Vincent, for their work on bacterial vaccines. A further sum is given to various ambulances and the remainder held in reserve. This prize was established in 1899 by Daniel Osiris, who established a fund whose income should be used triennially to award a prize of about \$20,000 for the most remarkable work or discovery of general interest.

AMERICAN GYNECOLOGICAL SOCIETY.—The fortieth annual meeting of the American Gynecological Society is being held at the Greenbrier White Sulphur Springs, West Virginia, on May 18, 19 and 20 of the current week. The presidential address was made by Dr. Thomas J. Watkins of Chicago at the morning session on May 19. On May 20 a joint session is to be held with the American Association of Genito-Urinary Surgeons at which, among others, addresses are to be made by Dr. Hugh Cabot and Dr. A. L. Chute of Boston on errors in the diagnosis of renal and urethral calculi and of renal infections.

UNIVERSITY OF NEBRASKA MEDICAL SCHOOL.—It is announced that the thirty-fourth session of the Nebraska State Legislature, which recently adjourned, has appropriated the sum of \$150,000 for the erection of a teaching hospital in conjunction with the University of Nebraska Medical School at Omaha.

NATIONAL COMMISSION ON MILK STANDARDS.—The annual meeting of the National Commission

on Milk Standards was held in New York on May 6. This commission, composed of prominent public health officials and sanitarians, was appointed in 1911 by the New York milk committee to recommend standards of milk and milk products. Among its members are Dr. Carl L. Alsberg, chief of the bureau of chemistry of the United States Department of Agriculture; Dr. John F. Anderson, director of the hygienic laboratory of the United States Public Health Service; and Dr. A. D. Melvin, chief of the bureau of animal industry of the United States Department of Agriculture. At its recent meeting the commission adopted a series of recommendations for new sanitary standards and regulations to govern the manufacture and sale of ice cream, butter and condensed milk. In an announcement made by the commission is the statement that "it is now known that all of the dangerous diseases spread through infected milk are also spread through ice cream and butter. In fact, these products offer a good medium through which germs of typhoid fever, tuberculosis, diphtheria, scarlet fever, septic sore throat and other infectious diseases may be transferred from diseased animals and handlers to consumers."

In this connection it is interesting to note the superiority of the milk supply in the District of Columbia, and its freedom from epidemics due to milk. It is controlled by a commission appointed by the President, consisting of three members whose jurisdiction extends over the police and health departments. The results obtained have been the more noteworthy in view of the fact that 85 to 90% of the milk supply comes from outside the district, and, while 85% of this comes from Maryland and Virginia, the remainder comes from Ohio and southern New York. None of this, however, is over 48 hours old. Washington inspectors have the benefit, of course, of the federal pure food law as well as their local regulations, and put them in force by inspection of every dairy that sends milk to Washington for sale.

EUROPEAN WAR NOTES.—Report from Washington, D. C., on May 6 announces an anonymous gift of \$10,000 for use by the American Red Cross "on the field of action in the European war, wherever the society may find the need most urgent and without regard to the nationality of those whom it may benefit."

On May 6 a party of eighteen nurses sailed from New York on the steamer *Philadelphia* for Boulogne, France, where they will work in field hospitals under the French Red Cross.

On May 8 Dr. Sherman Dunn sailed from New York aboard the French liner *Espagne* for Bordeaux, France, to serve with an American Red Cross unit at Amiens and at a base hospital near Ypres.

On May 15 a party of four physicians, one sanitary engineer and ten sanitary inspectors sailed from New York aboard the *Athenia* for service in the suppression of the typhus epidemic

in Serbia. The physicians of the party are Dr. Henry D. Neagle, Dr. A. F. Cornelius, Dr. S. H. Osborne and Dr. Harold H. Mitchell.

On May 8 Miss Mabel T. Boardman, national chairman of the American Red Cross, issued at Washington the following statement based on despatches from Dr. Richard P. Strong, head of of the American Sanitary Commission engaged in the suppression of typhus fever in Serbia:—

"The American Red Cross has received several despatches from the Sanitary Commission, which it sent to Serbia in coöperation with the Rockefeller Foundation. In the first despatch Dr. Strong reports that he believes the epidemic controllable in a comparatively short time under proper measures. There existed no central organization when he arrived there. The British, French and other organizations were each acting independently. He at once arranged to organize a central health board, and to introduce, with the government's support, proper measures of control. The work includes Montenegro, where also typhus is epidemic.

"On April 26, Dr. Strong reported that a board of health had been organized, with Prince Alexander as its president, Sir Ralph Paget as its vice-president, and Dr. Strong medical director. The chiefs of the French, Russian and English commissions and members of the military and civil medical departments of Serbia constitute the board. In this cable Dr. Strong asked for 500 clinical thermometers for the Serbian Red Cross, as there were only sixty in the country and none could be obtained in Europe. These the American Red Cross is arranging to send. He asked also for the twenty-five doctors or medical inspectors of sanitary work and a sanitary engineer, also the supplies that are being sent.

"In a cable of April 27 Dr. Strong made an additional request for 150 doctors, inspectors, or fourth-year medical students for the Serbian Government. He asked for cholera vaccine, for a bill was about to pass making cholera vaccination compulsory. The Red Cross is sending on the 13th. 12,200 doses of this vaccine. It sent a small shipment with the personnel that sailed some time ago. In the last despatch Dr. Strong said that the work was progressing favorably and harmoniously."

On May 15 the totals of the principal American relief funds for the European War reached the following amounts:—

New England Belgian Fund.....	\$256,253.65
Massachusetts Red Cross Fund...	134,200.95
New England Jewish Fund.....	61,974.86
Boston Polish Fund.....	45,596.54
Boston Serbian Fund.....	29,366.25

It is stated by the New York commission for relief in Belgium that the total of the cash and cargoes (in value) contributed in America, for distribution by the commission, now amounts to \$60,644,355.00. The total weight of foodstuffs and clothing amounts to 674,876 tons.

BOSTON AND NEW ENGLAND.

SUBSCRIPTION DINNER TO DR. SMITH.—It is announced that the postponed subscription dinner to Dr. Theobald Smith will be held at the Harvard Club on Wednesday, June 2, at 7 p.m. All physicians who desire further information about this dinner should communicate with Dr. Marshal Fabyan, 379 Commonwealth Avenue, Boston.

TRANSFER OF BOSTON QUARANTINE SERVICE.—On May 10 a lease was signed by Mayor Curley and by Dr. L. E. Cofer, the latter representing Surgeon-General Blue of the Public Health Service, providing for the transfer of the Boston Quarantine Service to the federal health authorities on June 1. The terms of the lease are based on a nominal rental of \$1.00 for the first year, at the expiration of which time it is expected that Congress will pass an appropriation for the purchase of the quarantine property at a price to be fixed by arbitration, presumably about \$200,000.

CHILDREN'S HOSPITAL TRAINING SCHOOL.—The annual graduating exercises of the Children's Hospital Training School of Boston were held at the Harvard Medical School on Thursday afternoon of last week, May 13. Diplomas were awarded to a large class of pupil candidates.

PHYSICAL CONDITION OF HARVARD FRESHMEN.—Dr. Roger I. Lee, professor of hygiene at Harvard College, has recently submitted a report presenting the result of a physical examination of the 662 members of the freshman class. Of these 288, or 43½%, had had some previous operation for trouble with the nose or throat. There were 273, or 41%, who wore glasses, and of these 108 wore them constantly. Forty-one, or 6%, had been operated upon for appendicitis; 20 presented lesions of the lungs, of which 12 were tuberculous; and 19 had some form of valvular disease of the heart. Thirty-three had never been vaccinated against smallpox. Only one had serious dental caries. The average age of the students examined was 18, the average weight 136 pounds and the average height 5.8 ft. At the conclusion of his report Dr. Lee writes in part as follows of the results and value of this examination:—

"One usually receives general impressions from a survey of this sort that cannot be put down in statistical form. The marked general impression which I gained from the completed examination of these 662 freshmen was that they made up a very healthy, wholesome group of young men.

"It had been the expectation that probably the real value of this examination would be the detection of a certain amount of disease which, if detected early, could be cured. We were able

to discover in a number of students conditions that have subsequently been corrected. We have also detected certain impairments which require observance and guidance, probably throughout the college course. This is already being done.

"But the greatest value of this examination, to my mind, and with this I have been very strongly impressed, is not so much the detection of existing disease, as the assurance of a larger group of boys, who think that they have disease, that they are really sound. Curiously enough, there were more boys who thought they had a serious organic defect, usually of the heart, and were found entirely sound, than boys who thought they were well and had disease. In many instances boys were worrying over ailments that were purely fanciful, but this worry was having a considerable effect on their general condition. The importance of the compulsory physical examination seems to be as much the correction of erroneous ideas concerning disease in the healthy as the detection of disease."

NURSING ASSOCIATIONS IN AMERICA.—In an address before the recent Massachusetts Health Conference, Miss Ella Phillips Crandall of New York presented statistics of the nursing associations and their work in America. In 1901 there were only 53 such organizations and only 136 nurses in the United States doing what may be termed community nursing. The municipal nurse was hardly known. There are now 2,066 nursing organizations in the United States and over 5000 nurses serving under departments of health or education, philanthropic organizations, insurance companies, and industrial and commercial agencies. The work of these nurses is primarily educational and prophylactic. The Boston Instructive District Nursing Association is recognized throughout the country as the pioneer organization in work of this sort.

REPORT OF THE NORFOLK STATE HOSPITAL.—The recently published first annual report of the Norfolk State Hospital for the treatment of inebriate patients and drug habitués contains the following information: There were 550 new cases received since June 1, 1914, the date of the opening of the hospital, 450 of whom were voluntary and 100 committed by the courts. In January, 1914, a permanent out-patient office was established in Boston, and because of its great value to the out-patient department of the hospital its extension is strongly recommended. The out-patient department of the hospital submits the following figures: visits to office, 471; visits to hospital, 105; visits to homes of patients who have been discharged from the hospital, 2770; visits to employers relative to work for discharged patients, 130; situations obtained for discharged patients, 97; men who are abstinent and working, 1188; men who are abstinent, but not working, 227; men who

are drinking some, but working, 295; men who are drinking and not working, 472.

MONSON STATE HOSPITAL.—The trustees of the Monson State Hospital report for the year ending Nov. 30, 1914, an average number of patients of 943, of which 96 were discharged and 62 died. Eight hundred and twelve patients were employed in various ways about the hospital and the report contains a long list of articles made by patients in the sewing and industrial rooms. Appropriations for the enlargement of the administration building, for increasing the supply of surface water and for the purchase of an electric outfit are requested.

FOOT AND MOUTH DISEASE QUARANTINE IN NEW ENGLAND.—Report from Washington, D.C., on May 7, states that the National Department of Agriculture ordered the foot and mouth disease quarantine entirely raised in New Hampshire on May 10 and the restrictions in the quarantine area in Rhode Island modified on the same date.

HOSPITAL BEQUESTS.—The will of the late Frances Bartlett, of Boston, which was filed in the Suffolk Probate Court on May 7, contains a bequest of \$24,000 to the Boston Instructive District Nursing Association, the income to be used to support a nurse under direction of the Boston Lying-in Hospital, the fund to be available so long as the association and hospital coöperate, and when they cease to coöperate the income to be used to support one or more nurses for the association. The will provides that when the association ceases to carry out the purposes of the bequest, then \$14,000 of the fund shall go to Harvard and the balance to the Lying-in Hospital.

The will also contains a bequest of \$20,000 to Harvard College to support two scholarships, one for the college, the other for the Harvard Medical School. The will also contains a remainder providing that Harvard shall receive the income of the residuary estate, to be applied equally for the maintenance of scholarships in the college and in the medical school.

Gifts have been announced to the sum of \$72,908 to be devoted to cancer research at the Harvard medical school. Of this amount, \$50,000 is provided by a bequest in the will of the late Philip C. Lockwood of Boston.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending May 11, 1915: Diphtheria, 64, of which 9 were non-residents; scarlatina, 70, of which 6 were non-residents; typhoid fever, 7, of which 1 was non-resident; measles, 160, of which 10 were non-residents; tuberculosis, 56, of which 2 were non-residents. The death-rate of the reported deaths for the week was 17.97.

Massachusetts Medical Society.

THE LABOR CLEAN MILK BILL.

THE President of the Massachusetts Medical Society has recently sent to every member of the Society the following circular letter, relative to the Labor Clean Milk Bill (Senate No. 482), which has been editorially advocated by the JOURNAL, and the text of which appeared in our issue of Feb. 25, 1915:—

“My dear Doctor:—

The Labor Clean Milk Bill advocated by the Massachusetts Medical Society will soon be laid before the Governor for his signature.

Will you please write to His Excellency, David I. Walsh, Governor, expressing the hope that he will sign this most important health measure.

It will enable the State Department of Health to enforce its suggestions for cleanliness in connection with the milk supply, something it cannot do under existing law. It also abundantly safeguards the rights of the producers and handlers.

It will be valuable to local boards which have not adopted dairy regulations, as they can invoke its aid to require unhealthful conditions to be cleaned up.

It is desirable that you should write the Governor as soon after the receipt of this letter as possible.

Very truly yours,
CHARLES F. WITHINGTON, M.D.,
President.”

Miscellany.

TRIENNIAL MEETING OF THE HARVARD MEDICAL ALUMNI ASSOCIATION.

THE triennial meeting of the Harvard Medical Alumni Association which is being held in Boston today affords an opportunity for both remote and recent graduates to observe the advances which have been made in the various departments of the school, in its affiliated hospitals, and in the other hospitals of the city. In the morning there will be operations and demonstrations of cases by members of the various staffs at the Massachusetts General, Boston City, and Psychopathic Hospitals, and at the Free Hospital for Women. At the Massachusetts General Hospital from 11.25 a.m. to 12.30 p.m., the following special reports of investigations will be given:—

- (1) A New Preparation for Making Injected Radiographs, by Dr. E. L. Young, Jr.
- (2) The Value of Cardiography in Diagnosis, by Dr. P. D. White.

- 3) The Clinical Value of Urobilin Estimation in the Stools as an Indication of Blood Destruction, by Dr. O. H. Robertson.
- 4) The Clinical Study of the Blood Flow, by Dr. J. H. Means.
- 5) Splenectomy in Pernicious Anemia, by Dr. R. I. Lee.
- 6) Types of Pneumococci in the Mouth in Normal Individuals in relation to the Etiology of Lobar Pneumonia, by Dr. F. T. Lord.
- 7) The Heart Muscle in Pneumonia, by Dr. L. H. Newburgh.

At the Boston City Hospital the following special demonstrations will be given:—

- 10.00 a.m.—Surgical Amphitheatre. Demonstration of X-ray Findings in Pericarditis, Drs. Sears and Palfrey.
- 10.15 a.m.—Use of the Duodenal Tube in Diagnosis and Treatment, Dr. F. W. White.
- 10.30 a.m.—Cases of Obscure Mediastinal Lesions, Dr. Cleaveland Floyd.
- 10.45 a.m.—Demonstration of Cases of Fat Transplantation, Drs. Lund and Loder.
- 11.00 a.m.—Technic of Blood Transfusion with Glass Cylinders, Dr. A. R. Kimpton and J. H. Brown, Ph.D. (Illustrated by moving pictures.)
- 11.15 a.m.—Observation on Blood Pressure, Dr. Cadis Phipps.
- 11.00-12—Pathological Laboratory. Demonstrations of Cutaneous Infection caused by a new fungus (*Phialophora verrucosa*). Dr. E. M. Medlar.
Demonstration of Cross specimens preserved by the oil (modified Kaiserling) method.

In the afternoon there will be similar demonstrations at the Peter Bent Brigham, Children's and Huntington Hospitals. At the Harvard Medical School the various departments will be open for inspection from 2.30 to 5.30, and the following special demonstrations will be given:—

- 3.00—Department of Physiology.
 - (1) Electrical Changes in Contracting Muscle, by Dr. Alexander Forbes.
 - (2) Quantitative Electrical Stimulation applied to Human Beings, by Dr. E. G. Martin.
 - (3) Experimental Exophthalmos, by Prof. W. B. Cannon.
- 3.30—Department of Hygiene and Preventive Medicine.
Ten-minute talks by each man in the department upon the problems at which he is now working.
- 4.30—Amphitheatre, Building D.
Syphilitic Diseases of Bones, with lantern slide demonstration, by Dr. E. H. Nichols.
- 5.00-5.30—Bone Changes in Rickets and Allied Conditions, with lantern slide demonstration, by Prof. R. W. Lovett.

The triennial dinner will be held at the Harvard Club at 7.30 p.m. The principal speakers will be Dr. H. P. Walcott, Dr. Leonard Wood, Dr. E. H. Bradford, Dr. H. D. Arnold, Dr. Haven Emerson and Dr. F. W. Peabody. All alumni, whether members of the association or not, are cordially invited to attend, and tickets at \$3.00 each, may be obtained at the dinner by those who have not already procured them. This triennial gathering of Harvard Medical graduates is an occasion, not only of pleasure and profit to them, but of advantage to the school to which they owe their medical training. It is earnestly to be hoped that every medical alumnus who can possibly make arrangements to attend any or all of the functions of this day will do so, not for his own sake alone but for that of others and of the school.

Correspondence.

PARIS LETTER.

MILITARY DEATHS AND FUNERALS IN PARIS.

(From Our Special Correspondent.)

PARIS, April 24, 1915.

Mr. Editor: It is a curious thing to observe the unsuspected strength of the callous side of human nature. In times like this, when all around us we hear of little else than misfortune or woe, we so quickly grow used to them that nothing short of an actual calamity any longer makes an impression. A large percentage of the women here are in mourning; everyone you speak to has lost relatives, one or several; out of six men mobilized in the house in which I live, three have been wounded, two very severely; my maid has had one cousin killed, and another is down with typhoid fever; and on the streets the sight of blind, maimed and disabled soldiers, all of course young and in the very prime of life, is incessant. After six months of this sort of thing it is really perhaps not surprising that we should have become unfeeling pachyderms.

There is, however, one sight that never fails to make a deep impression on me,—the simple, military funeral-convey of the soldiers who die in the ambulances here; it is, I imagine, this very simplicity that goes so far toward the extraordinary effect produced. Many of these gallant men have given up their lives for their country in utter silence, and die surrounded by entire strangers, their relatives in remote provincial villages often never even hearing what their fate has been. The importance which the French attach to the three great functions of life, births, marriages and deaths, is, of course, well-known; they were not the people, therefore, to allow these unfortunate victims of war to be whisked away surreptitiously and buried in some obscure cemetery without any of their beloved formalities. It was in consequence arranged by warm-hearted residents with the authorities that a regular funeral was to be accorded to each soldier dying in the Paris ambulances, even though he had not a friend, or a cent to his name. This thoughtfulness goes to show how difficult the French character is to understand, on account of its unexpected many-sidedness; for, in general terms, the Frenchman is not a kind person, at any rate as we comprehend the term. On the contrary, from our viewpoint he is

rather cold and hard. Yet this burial trait is simply charming. Here is what you see on the streets pretty much every day: A simple but nice open hearse, bearing the coffin shrouded in the beautiful national colors, and with a few flowers; the little procession is preceded by the usual municipal representative in dress suit, cocked hat and scarf of office; on either side walks the picket of honor with rifles reversed; and the rear is brought up by the indispensable cortège of mourners, who in this case, however, have to be purely people of good-will, soldiers, police, nurses in uniform, sisters of charity, and finally a few curious-looking elderly men and women, none of whom seem to know each other, and who have a general air of wondering how they came to be there. I have been told that there is a sort of confraternity of men and women with big and tender hearts that make it their regular business to follow to the grave the remains of these noble sons of France. They have probably reasoned within themselves that it will be a certain source of consolation to many a mother's heart throughout the land to feel that if her son is one of the many who breathe their last in the Paris military wards, he will at least be buried with ceremonious respect.

These funerals proceed at a measured pace. The invariable custom here is, even in times of peace, for the men on the sidewalks to touch or raise their hats as a cortège passes, and for the women to cross themselves. But now it is quite a different affair. As the picket of ten surrounding the tricolor goes slowly along, the passers-by on either side step to the edge of the curb, stand at attention and bare their heads. Many of them are former soldiers, and display in their buttonholes the green and black ribbon of the campaign of 1870. And as they line up there, giving the last salute to their younger comrade of this war of liberation, you suddenly observe a fact that the custom of wearing hats in the street had hitherto kept from evidence: that most of the men in Paris now are either gray, white or bald! All of the younger set are under arms. In a word, it is one of the most impressive scenes I have witnessed for a long while, and I am not ashamed to own that my eyes are moist each time it is given to me to be a spectator at one of these "last posts."

It is reported that at one of the recent ordinary civilian funerals an incorrigible Paris *garroche* was heard to murmur to himself: "Well there's a chap who could not have been very inquisitive!"—The hidden meaning of the remark being, of course, that it would worry him, *garroche*, more than a little to have to die just at this juncture, and not to live to see the end of this campaign and to learn what the peace terms will be. Think of departing to Abraham's bosom, for instance, with a wretched attack of pneumonia, as was the case with poor Lord Roberts, and never knowing how the war ended, what compensation was granted to Belgium and what her future frontier is to be; without reading of the re-uniting after more than a century of the three fragments of the Kingdom of Poland; without a knowledge of whether the former wrong to Denmark was made good, or the two provinces wrested from her by the joint attack of Austria and Germany in 1864 returned to her; and, last but by no means least, without being here to see the little men in red trousers make their delirious re-entry up the Avenue du Bois and down the Champs Elysées.

Among all the deaths that have occurred of late, two strike me as beyond all measure sad. The first is that of Paul Deroulède, the enthusiastic, indefatigable patriot and apostle of the Revanche. What a cruel irony of Fate that this generous son of the generous race should have been able to keep up his belief in the future return to France of the two lost provinces through all those dark and hopeless years, during which there seemed to the general outsider to be about as much prospect of the realization of this

idea as of the annexation of the planet Mars,—only to die six months before the outbreak of the hostilities that would have brought to him the dearest wish of his heart! And here again can be cited a noble and kindly deed to the credit of the French arms. When the first French *chasseurs* crossed the boundary of Alsace they at once threw down the German frontier-post, with its eagle and "Deutsches Reich," despatched it off to Paris, and had it fastened to the wall as a trophy over Paul Deroulède's grave in the modest little cemetery of La-Celle St. Cloud!

The other death is that of Lord Roberts. In a way it was a fine one, the death of a soldier among his brethren in arms, even if he did die of illness. But a cruel blow it must have been, all the same, to be carried off without seeing the end of such hostilities as these, the greatest in all history.

"S."

THE TREATMENT OF GUNSHOT WOUNDS OF THE LUNG.

DENVER, COLO., April 28, 1915.

Mr. Editor: Twenty-five years ago I had a case of gunshot wound of the lung in which slow but constant hemorrhage through the bronchial tubes in a few days carried my patient along "the trail of souls departing to the Spirit Land" (as the Indians call the Milky Way).

At that time I was making many post-mortems and I noticed the resiliency of the lung tissue and the way in which the lung collapsed and contracted when air was admitted to the thorax.

I thought then this idea might be made use of in handling gunshot wounds of the lungs, namely, to allow the contraction of the lung to constrict and close the blood vessels in selected cases, where too large blood vessels were not involved, until the blood vessels were filled with an organized clot after which the lung could be allowed to expand.

Since that time I have had under my care a famous U.S. naval officer who told me that in the Puget Sound country he had pleurisy with effusion but it was not discovered until he told his attending physicians that he felt as if his left lung were "jammed under his left ear."

I have had a New York Wall Street broker in Denver for tuberculosis of the lung develop a pneumothorax of the left side which pushed his lung over so hard that the heart's apex beat was beyond the sternum on the right side.

Aspiration, with a hiss of escaping air through the hollow needle like escaping steam, converted his respiration from 47 to 17, and a good night's sleep relieved an agony of 48 hours, and the patient recovered.

A case of empyema of the left side which came to me from the Philippines right after the Spanish war in which so many quarts of pus were evacuated by incision through the skin, made in a sitting posture (the patient could not lie down), and a thrust of a trochar into the thorax while only half etherized and nearly in collapse sent the pus spurting with such force that the first basin to catch it had to be held three feet away from the wall of the chest, the next basin two feet away, the third one a foot away, or the pus would have spattered into our eyes. (I had no rubber tubing with me for my trochar.) The patient recovered.

Now, if human beings can live with the chest cavity of one side filled and distended with pleuritic fluid, with air, or with pus, they can live with an artificial pneumothorax or with a chest distended with salt solution or filled with air alone without any pressure, as in a bad empyema before resection of ribs.

Why cannot artificial pneumothorax or distention with normal salt solution be used to compress certain selected, otherwise fatal, gunshot wounds of the lung until hemorrhage ceases and the wound heals after which the thorax can be aspirated and the lung allowed to expand or the thorax can be handled as an empyema?

Upon the firing line or just back of it, where other conveniences for pumping air or sterile salt solution were not at hand, air could be pumped into the pleural cavity with a rubber tube and a bulb (a No. 1 Davidson syringe would do) and the bullet hole or holes plugged with gauze covered with rubber tissue.

Even no pressure of air may be required. Simple admission of air to the thorax may allow the lung to retract and contract and close the bleeding vessels, and overcome the expansile thrust of the contracting right ventricle.

I have waited long for another gunshot wound of the lung. I may never have one. Perhaps this letter may reach the eye of a surgeon in Europe or America who might consider the idea worth trying.

Very truly yours,

O. J. PFEIFFER, M.D.

THE NASO-PHARYNX AS A PORTAL OF ENTRY FOR AIR-BORNE INFECTIONS.

COLONIAL BUILDING, BOSTON, May 6, 1915.

Mr. Editor: It is evident that you must have had your "ear to the ground" when you wrote the timely editorial, in the JOURNAL for even date, upon the sore throat epidemic in Dorchester and Milton. I cannot conceive of better advice to be given in the absence of direct evidence. As Professor Flexner has proven that epidemic poliomyelitis is conveyed by germs (or spores) entering or leaving the naso-pharynx as I have been suggesting in regard to what I insist upon calling air-borne infections, so in these "septic sore throat" cases there can be no other way of explaining their etiology. I personally investigated a similar epidemic which "broke out" in a large boarding school for boys, situated two miles from a city where other cases had occurred simultaneously. In the case of the boarding school it was very plain that the milk supply being local was "above reproach." There was, however, a single meteorological feature involved which could not have been satisfactorily explained had the observer entered the city from the North. There was snow upon the ground everywhere in the vicinity. The last storm to pass over the state had come from the South and Southwest. It had previously passed over uncovered territory with "slight precipitation." This territory, about 75 miles south, included an area previously "infected" where having been some "mild sore throats" reported herein. It is on record that an extensive and very severe winter storm which had moved northwards across Europe from Italy left in its wake "great precipitation." It is also known that such storms purify the air and this was true in this instance, but the severity and intensity of the storm set up vortices and "holes" in the air which were "filled up" by injected air from areas outside the storm-belt. There resulted a visitation of the influenza, and Munich, Vienna, Dresden and even more northern cities reported an epidemic of La Grippe.

Judging from this and other observations and having had great clinical experience with diseases whose original 'nidus' is unquestionably the rhino-pharynx and specifically that portion which includes the hypopharynx, I re-assert that it is practically impossible to conclude that such diseases, to include "streptococcal septic 'sore throat' or septic tonsillitis," first enter the economy through the alimentary canal.

EDMUND D. SPEAR, M.D.

THE POSSIBLE SYPHILITIC ORIGIN OF CERTAIN BLADDER ULCERATIONS.

Boston, May 7, 1915.

Mr. Editor: In the JOURNAL for May 6, Dr. Hunner records an interesting series of cases of bladder ulceration in women, all carefully studied and no definite cause found for their appearance. In the discussion of his paper, also in the JOURNAL, there is no mention made of the possibility of syphilis being the cause of these ulcerations. Rheumatism and tonsillitis were considered, but not incriminated. Certain points in the history of the cases (Italics mine) are of interest in this connection. In the first place, the *chronicity* of the ulcers or symptoms which were *probably* due to the ulcers without any tuberculosis being found; thus one case, Case 3, had been treated for bladder trouble 20 years ago. Case 5, bladder symptoms for 6 years; Case 6, *nocturnal enuresis* up to the menarche; Case 7, bladder symptoms *as long as she can remember*; Case 8, *severe temporal headaches* since childhood. Dr. Hunner, speaking of the cystoscopic picture, alludes to the smooth, white scars of former ulceration. Smooth white scars in other parts of the body are at least suggestive of healed gummata. He says: "Our conclusion, therefore, is that the diagnosis of this peculiar form of bladder ulceration depends ultimately on its *resistance to all ordinary forms of treatment*." In speaking of the pathologic picture, he says: "In some of the specimens this granulation tissue is fairly richly supplied with capillaries, but in most of them there is a preponderance of connective tissue and infiltration of small round cells and leucocytes." This latter is more or less suggestive of gummatous ulceration. In the light of the suggestive, but in no way positive, symptoms and clinical evidences, it would seem as if syphilis was a possible, even a probable, factor in some or all of these cases.

Let us recapitulate. Ulcerations of *very long standing*, not malignant, not tuberculous, with certain suggestive symptoms of possible congenital syphilis in some of the cases. White, smooth, scars, with a pathologic report not incompatible with gumma. Certainly with no other definite cause found, syphilis should be considered very strongly in these cases. It is not too much to say that a series of Wassermann's in cases of doubtful bladder ulceration, would show a considerable percentage of unrecognized syphilis.

Very truly yours,

WM. PEARCE COUES, M.D.

NOTICES.

DOCTORS FOR DUTY IN A BRITISH BASE HOSPITAL.

Harvard, Columbia and Johns Hopkins Universities propose to provide a surgical unit to take charge of a base hospital for British wounded, and for that purpose there is desired a staff of thirty-two surgeons; sixteen of those will preferably be well trained fourth-year graduates or house-officers having just completed a surgical service. The expedition will start between June 5 and 15. The Harvard contingent will take the first detail for a minimum service of three months. Preference will be given to men willing to stay six months.

The service will be either in England or in France, depending upon exigencies. Transportation both ways will be paid, and men will be given regular army pay. Men wishing to join the expedition will please apply in writing to Dr. Edward H. Nichols, 294 Marlboro Street, or to Dr. C. A. Porter, 254 Beacon Street, or to Dr. Wm. E. Faulkner, 290 Marlboro Street, stating their age, medical education and surgical training.

NURSES FOR DUTY IN A BRITISH BASE HOSPITAL.

Harvard, Columbia and Johns Hopkins Universities propose to provide a surgical unit to take charge of a base hospital for British wounded, for a period of six months. The expedition will start probably sometime between the first and the fifteenth of June.

For this unit there is desired a staff of seventy-six trained nurses, consisting of one matron, twenty-six sisters (head nurses), and forty-eight ward nurses.

Nurses will be paid regular army rates: sisters, "head nurses," 50 pounds per annum; staff nurses, "ward nurses," 40 pounds per annum. Free transportation to and from the hospital, probably an American ship will be provided.

The service will be for a minimum period of three months, and preference will be given to nurses agreeing to serve for six months. The service may be in England or in France, depending upon exigencies.

Nurses wishing to join this unit, will please apply in writing to Dr. E. H. Nichols, 294 Marlboro Street, Boston, stating their training and experience, with references to doctors for whom they have worked. Nurses who have had special operating room experience, will please so state.

FIFTEEN DOCTORS WANTED.

The American Board of Commissioners for Foreign Missions needs at once fifteen surgeons and physicians for work in mission fields. Nine are wanted for China, four for Turkey, one for Africa and, most urgent of all, one at once for relief work in Serbia, with station at Monastir.

For China, six men and three women are wanted to join hospitals already running which treat from ten thousand to thirty thousand cases a year. The new men and women will be associated with surgeons in charge.

In four hospitals in Turkey physician-surgeons are wanted in association with doctors already on the ground. The American hospitals have increased their influence enormously during these months of

war and the men on the ground must be re-enforced. In Durban, Africa, a physician-surgeon is urgently needed.

The Board lays down no sectarian test. The candidates should be not over thirty-five years of age. In equipment the Board requires a degree from a first-class institution and in addition an internship or its equivalent. Specialization is not demanded though special preparation is welcomed. Details as to service may be secured from Dr. C. H. Patton, 14 Beacon Street, Boston.

APPOINTMENTS.

UNIVERSITY OF CALIFORNIA.—*Dr. Samuel H. Hurwitz*, formerly of Boston, has been appointed instructor in research medicine on the George Williams Hooper Foundation for medical research at the University of California.

UNIVERSITY OF MICHIGAN.—*Dr. Albion W. Hewlett*, professor of medicine at the University of Michigan, has been appointed visiting lecturer on medicine at the Harvard Medical School and temporary visiting physician at the Peter Bent Brigham Hospital, Boston.

UNIVERSITY OF TORONTO.—*Dr. Andrew Hunter*, formerly of the medical department of Cornell University, has been appointed professor of pathological chemistry at the University of Toronto.

RECENT DEATHS.

DR. SIR WILLIAM RICHARD GOWERS, who died on May 4 at London, was born in 1845 and was a graduate of Christ Church, Oxford, and of University College, London. He was a Fellow of the Royal Society and of the Royal College of Physicians of London and was known as a neurologist of international repute. He had received the degrees of M.D. from Trinity College, Dublin, and LL.D. from the University of Edinburgh. He was consulting physician of the University College Hospital, London, and of the National Hospital for Paralyzed and Epileptic. He was a member of the Royal Society of Science of Upsala, Sweden, and an honorary member of the Society of Russian Physicians at Petrograd. The best known work by Dr. Gowers is his "Manual of the Diseases of the Nervous System."

DR. JAY W. SEAVER, who died recently in Berkeley, Cal., was born at Craftsbury, Vt., in 1855. He graduated from Yale College in 1880 and received the degree of M.D., from Yale in 1885. He was for twenty years director of the Yale gymnasium and was at one time president of the American Association of Physical Educators and of the Society of College Gymnasium Directors. He was a writer on physical development and physical education. He retired from active work in 1905.

DR. GARDNER CALEB HILL, who died on April 30, at Keene, N. H., was born at Winchester, N. H., in 1829. He studied medicine as an apprentice to Dr. Comings of Swanzey, N. H., and received the degree of M.D. from the Castleton (Vt.) Medical College in 1856. After practising his profession for a time at Warwick, Mass., he removed to Keene in 1867. He is survived by his widow.

DR. SETH WIGHT KELLEY died at his home in Woburn, Mass., May 5, from cerebral hemorrhage. He was born in Oxford, Me., June 26, 1848, and received the degree of A.B. from Dartmouth College in 1869 and M.D. from Harvard University in 1874. In this year he joined the Massachusetts Medical Society, and settled in Woburn. He had been chairman of the Woburn board of health and a member of the school committee. He is survived by his second wife and one daughter. Dr. Kelley was councillor from the Middlesex East District from 1891 to 1898.

Addresses

HOW THE PRACTISING PHYSICIAN MAY AID THE DEPARTMENT OF HEALTH.*

BY ALLAN J. McLAUGHLIN, M.D., BOSTON.

Massachusetts State Commissioner of Health.

THE practising physician has always been a great factor in the suppression of communicable diseases and his importance in public health work has been enormously increased in recent years because of the extension of public health work beyond the communicable diseases themselves.

The work of health departments and health officers has evolved from the suppression of contagious or epidemic diseases into the prevention of all disease and the business of keeping people healthy.

Wonderful progress has been made in the reduction of the general death rate and of the death rate for certain communicable diseases, notably, typhoid fever, tuberculosis and diphtheria.

Two great agencies stand out prominently in considering this great saving of lives, viz: the laboratory and the practical application of demography. Through these great agencies we have secured a better knowledge of the cause of disease, better knowledge of the prevalence of disease, and better knowledge of methods of prevention of disease.

The laboratory has given us exact knowledge of the causes of many diseases and has demonstrated how these diseases are transmitted. With this knowledge more precise and effective methods of combating these diseases have been devised and employed. Exact knowledge of the specific organisms which cause Asiatic cholera, typhoid fever, tuberculosis and diphtheria, and of the life history of these organisms, makes it possible greatly to reduce the mortality from these diseases, and to eradicate them under favorable conditions.

In the laboratory also we manufacture antitoxins and vaccines with which we cure or prevent these diseases.

Demography is second only to the laboratory as a factor in the great reductions effected in recent years.

By the practical application of vital statistics we learn in what localities and to what degree these diseases exist and are able to attack them more intelligently. These statistics also show what results, if any, are being attained.

The progress made and the great reductions effected, especially in typhoid fever, diphtheria and tuberculosis, are due in greatest measure to the improvement in public water supplies, the free use of antitoxin, and the splendid team work of various health agencies against tuberculosis.

The future reductions in the general death rate may be grouped under three heads, viz:—

1. Further reductions in the mortality from tuberculosis, typhoid fever, diphtheria, and some other communicable diseases, to the point of complete eradication.

2. Reduction in communicable diseases whose rates have not been materially reduced.

3. Reduction in the rates for infant mortality, cancer, and a number of diseases which are preventable, but not communicable.

The field of preventive medicine is so large

that I will not attempt to discuss all the problems in which your assistance is needed by the State Department of Health.

I will discuss briefly some of the diseases in which great success has already been achieved, and invite your attention also to some problems

which have been more or less neglected or upon which no concerted attack has been made.

Two things influence health officers in selecting the factors in mortality upon which it is best to concentrate their efforts:

1. The number of deaths due to the factor.
2. The possibility of effecting prompt and significant reduction in the death-rate for this factor.

TUBERCULOSIS.

The eradication of tuberculosis depends upon:

1. Acquiring control of the "open" cases and maintaining this control until the death of the patient.
2. In discovering incipient cases and preventing them from becoming "open" cases.

We have in Massachusetts two excellent laws calculated to facilitate control over open cases and the early discovery and efficient treatment of incipient cases.

The law relating to hospitals aims to secure control of tuberculosis cases in the dangerous stages by providing hospital care near their homes. A city or town may comply with this law in one of three ways:—

1. It may build a tuberculosis hospital.
2. It may make satisfactory arrangements with a neighboring hospital to care for its cases.
3. It may combine with one or more communities in building a joint hospital.

If this law is carried out so that the tuberculosis patients in the terminal months of their illness are cared for in hospitals, a further great reduction in the death rate may be expected.

The dispensary law provides that all cities and towns whose population exceeds 10,000 shall provide a proper tuberculosis dispensary, satisfactory to the State Department of Health.

It is unnecessary to make any argument in favor of the properly organized dispensary. Its utility is obvious in detecting incipient cases, in following up cured or arrested cases returned from sanatoria, and in advising and educating tuberculosis patients and their families in the prevention of the spread of the disease.

Both laws should be vigorously enforced, but there is less excuse for delay in the matter of the dispensaries because of the lesser expense involved.

TYPHOID FEVER.

The rates for typhoid fever have been reduced in Massachusetts from 45 in 1887 to 8 in 1912.

This probably means that water and milk have been almost eliminated as factors, and that we are facing the problem of getting rid of "residual" or "contact" typhoid. This is a very difficult task, as it depends upon the education of the individual. If all individuals considered themselves potential carriers of disease and cleansed their hands and finger nails frequently enough, thoroughly enough, and at the proper

times, typhoid fever would disappear from our statistics and become a matter of history.

In this matter of educating the individual in personal hygiene and his duty to his neighbor, the practising physician can be of inestimable value.

I wish to accentuate one other possibility in reducing our typhoid fever rate, viz: anti-typhoid inoculation. This should be encouraged by the practising physician, especially for people who travel much, and patients contemplating vacations. The citizen at home is able to protect himself to some degree, but when travelling is at the mercy of cooks and waiters in hotels, and on boats and trains.

DIPHTHERIA.

The rate for diphtheria has been reduced enormously by the use of antitoxin.

Earlier diagnoses, a broader use of immunizing doses of antitoxin to the contacts, and larger doses to the patient will still further reduce these rates, and these are matters which are in the hands of the practising physician.

SYPHILIS.

Exact knowledge of the prevalence of syphilis is not available but it is known to be widespread. Its effects upon infant mortality, insanity, blindness, tabes and general paresis are well known.

We have exact knowledge, thanks to the laboratory, of its cause, modes of transmission, and prevention.

The story of laboratory achievement in syphilis in the past ten years reads like a fairy tale.

In 1903 Metchnikoff and Roux successfully transmitted syphilis to the lower animals.

In 1905 Schaudinn discovered the cause of the disease, the *treponema pallidum*.

In 1906, Wassermann, Neisser and Bruck gave us the Wassermann reaction, which enables us to detect even those cases without external symptoms.

In 1910, Ehrlich gave to the world salvarsan, a specific destroyer of the *treponema*.

In 1911, Noguchi grew the *treponema pallidum* in pure culture, outside the body, and produced luetic of great diagnostic aid in very obscure cases.

In 1913, Noguchi demonstrated *treponema pallidum* in the brain of patients with general paresis, and in the cord of tabetic patients.

In spite of this exact knowledge of the etiology, prevention and cure of syphilis, we are not able to say that this scourge is being reduced. One glaring defect must be corrected, if only partly. Statistics are lacking and they are no less necessary in this disease than in others, if an intelligent campaign is to be conducted against it. In this the practising physician can be of the greatest assistance. The State Department of Health will make syphilis a reportable disease within a short time. Physicians will report details of

each case, omitting the name of the patient, as is the practice in New York City.

Very valuable information can thus be secured and a definite comprehensive program outlined for reducing the prevalence of this disease.

Because of our lack of statistics of venereal diseases, we are unable to say definitely whether these diseases are increasing or decreasing. I do not believe that anyone is rash enough to say they are decreasing.

I regard the question of syphilis optimistically. We know the cause of the disease and we have specific spirochaetocides. We must have early diagnosis, prompt treatment and treatment with supervision sufficiently prolonged to ensure a real cure. We must cease dallying with dusting powders and iodides in our clinics and make salvarsan and mercury, properly applied, available to all.

The accomplishment of this rests with the practising physician, and the credit for the enormous reduction which will follow in locomotor ataxia, in general paresis, in insanity and in blindness, will also be his.

PNEUMONIA.

The statistics for pneumonia are rather indefinite. We have in our official records bronchopneumonia, lobar pneumonia and pneumonia undefined. In 1912, for instance, there were 5300 deaths under these three headings in Massachusetts, of which 2200, or 41%, were children under ten years of age; about 900 deaths, or 16%, were recorded as lobar pneumonia between twenty and fifty years of age. Another large group includes the deaths in persons between the ages of fifty and eighty.

The first group, children under ten, includes hundreds of cases following whooping cough, measles, and other "benign" diseases of childhood. Too often children with whooping cough are permitted to go to school, ride in street cars and go to theatres and other crowded places.

The pernicious belief that children must have such diseases should be combated and every effort made to protect young children from exposure.

The widespread distribution of pneumococci in healthy individuals suggests that the specific organism requires certain assistance in producing the disease. These other factors in its etiology are not clearly understood, although we may surmise that they act by lowering the natural resisting power of the individual. Prophylaxis is further complicated by the many varieties of pneumococci, and the fact that pneumonia is not a simple problem. We understand little of the mechanism of immunity in pneumonia.

It would seem that normal, healthy individuals have a natural immunity against lobar pneumonia, but that this immunity is rather feeble and easily impaired or destroyed. This

is borne out by the fleeting character of the immunity produced by an acute attack.

For these reasons the development of efficient curative sera and of prophylactic inoculation is not very promising. The laboratory in the future will probably clear up the problem and give us the specifics which we need. In the meantime, cases of pneumonia should be treated as dangerous contagious diseases, the spread of which depends upon the secretions of the mouth and nose.

It seems certain that the natural immunity in normal healthy individuals may be nullified by dissipation, excesses and exposure to cold.

A cold shower and change to dry clothing would prevent many cases of pneumonia in miners, iron and steel workers, firemen, coal passers and many factory and mill workers. As a rule, however, these facilities are not available and the worker leaves the hot atmosphere of his work for the cold outer air in his perspiration-soaked garments.

A great many cases of pneumonia can be prevented by attention to personal hygiene, cold baths, living quarters not above 68° F., and cool sleeping rooms.

As teachers of personal hygiene, we must depend in greatest measure upon the practising physicians.

ORGANIC HEART DISEASE.

Two facts stand out prominently in the consideration of heart disease,—the large part it plays in our death rate and the fact that it is increasing instead of decreasing.

I realize that heart disease is an old acquaintance, but not usually considered a public health problem. Nevertheless, it is not so hopeless as generally believed, and in many cases it is a preventable disease.

Heart disease is not preventable to any great extent by official action, but a great many cases can be prevented by the wise counsel and activity of the practising physician who is thinking of preventive medicine.

Excluding congenital defects, a large percentage of deaths from organic heart disease up to the age of twenty years are preventable. A great many of these are due to what is called "rheumatism." We need more light on the etiology of rheumatism, but we are reasonably certain of the importance of diseased tonsils and pharyngeal tissue in its etiology. We also know the constant association of tonsillitis, rheumatism and damp insanitary housing conditions.

Examinations of school children reach a great many of these cases, but there is no reason why a great many more examinations of young children should not be made by the family physician without waiting for the tonsillitis or the rheumatism or the valvular lesion actually to manifest itself.

Advice should be freely given to prevent the delicate child from overstrain by sudden violent

exercise, without proper preparation, or by entering a vocation for which he is physically unfit.

Physical exercise is of the greatest value if the exercise is properly suited to the patient, but we have seen in Marathon races, entry permitted to ill nourished youths with no preliminary preparation whatever. Exercise these boys need, but certainly not that kind of exercise.

There is a class, however, which is in even greater need of advice than the ill nourished and underfed. It is the overfed man who has no time for exercise, but who works long hours at high pressure, with perhaps heavy responsibilities and many causes for worry. With proper insistence in these cases, many valuable lives could be saved for an additional twenty years of usefulness which are now lost between forty-five and fifty years of age.

CANCER.

Cancer is one of the big factors in our mortality, and like "heart disease," is increasing instead of decreasing.

While our knowledge of its etiology is somewhat obscure, we have enough knowledge, if properly applied, to reduce greatly its ravages.

Cancer is a preventable disease if discovered early and promptly operated upon. There are several reasons why early discovery and prompt action are the exception rather than the rule. The early lesion is painless and we are not looking for it. When it is found, dislike of a cutting operation results in palliatives and delay. In no other disease, perhaps, is procrastination followed by such appalling results.

We should be looking for cancer because when the patient seeks us, it is usually too late. We must look with suspicion upon bleeding piles and uterine hemorrhages, or breast tumors after middle life, or any sore or swelling on the lower lip or tongue.

In addition to acquiring the attitude of looking for cancer and advising immediate action, the physician should seek to prevent cancer by removing one of the contributory causes, namely, local irritation.

Irritation of the tongue from broken teeth or rough pipe stems often occurs, and if warts or moles are subject to irritation they should be removed.

We must not regard lightly gastritis and gastric ulcer. A great many cancers grow from the site of a neglected or imperfectly healed ulcer, and the seriousness of frequent attacks of indigestion should not be minimized.

In an ideal health organization the practising physicians must be considered as health officers. I believe the physician has a moral, if not a legal, obligation to discharge some of the duties of a health officer. He cannot restrict his activity to curative medicine, but must practice preventive medicine also.

In practising preventive medicine, like his brother, the health officer, he must not restrict his activities to communicable diseases alone, but must extend his efforts to the prevention of many diseases which, although not communicable, constitute great public health problems.

The physician's aid to the health department in quick and accurate diagnosis, and prompt reporting of cases is invaluable, but no less valuable assistance may be rendered by the physician as an educator.

I am sure that all practical health officers have found that the greatest defect in the average health organization has been the lack of a medium for carrying sanitary instructions into the home.

It matters little which disease or problem we may be considering, after the officials have eliminated all factors which are corrigible by official action, there remains always a group of factors which can be eliminated only by the enlightened coöperation of the individual families or of the individual members of those families.

Let us consider typhoid fever as an example. It is possible by official activity to install and maintain a safe water supply. It is possible to reduce the danger of infected milk to a minimum by official acts alone. In fact, if the eradication of typhoid fever depended upon the elimination of the water and milk factors alone, typhoid fever could be made to disappear from our statistics with comparative ease.

Unfortunately, after the water and milk factors are eliminated, there remains a group of factors responsible for what is called contact, or residual, typhoid, which is very difficult to reach. The only way these factors, including fingers, food, and flies, can be reached is by instruction in personal and family hygiene.

We do not "catch" typhoid, we "eat" it. That is, it is handed to us with our food or drink.

Transmission of disease by means of fingers and food is the method by which these diseases were perpetuated and handed down from remote ages to the present day. It was the method which perpetuated these diseases under primitive conditions when men lived in caves and huts, and when public water supplies and great milk industries did not exist. And today, whenever conditions approach the primitive, where poverty compels the overcrowding of filthy tenements, we find these factors most active in perpetuating disease.

To secure the instruction of such people, to raise their standard of personal hygiene, is the most difficult problem which today confronts the health officer. It is manifestly impossible for the health officer personally to educate all classes in a community in personal and family hygiene.

Printed literature is of great value, but does not solve the problem, which in most cases demands personal instruction for its solution.

The two most promising agencies for carrying the gospel of public health into the home are practising physicians and visiting nurses. I will not attempt to estimate the relative importance of these two agencies, but I desire to accentuate the opportunity for rendering a great public service which is here presented to the practising physician.

The function and value of the practising physician may be likened to the antibody in the patient's blood which brings the complement into relation with the invading organism. In the blood of a normal individual there is sufficient complement to destroy infection, but without the antibody it cannot reach, combine with, and destroy the infection.

So in a health department. The potentiality to eradicate disease as represented by knowledge of preventive medicine exists, but cannot be applied in the tenement or slum unless some combining influence is available to bring this knowledge into the home in a way that the ignorant can understand.

Let us have an application of the knowledge we possess, and utilize the specific remedies and prophylactics which the laboratory has given us.

Aid the health authorities to secure accurate statistics! Help to prevent epidemics and unnecessary spread of disease by prompt reporting of cases!

Prevent the spread of the diseases popularly supposed to be benign, as whooping cough, measles and influenza, but which are really responsible for hundreds of deaths.

Educate your patients in the necessity of right living. Show them the suicidal effect of overfeeding, lack of exercise, and living in overheated, ill-ventilated rooms. Try to prevent the national fault of running the machine at high speed and under high pressure all the time, without proper relaxation, rest and exercise. Do what you can also to correct another national fault, that of placing a square peg in a round hole. The ill-fed, narrow-chested youth who should be "punching cattle" should not be permitted, without protest, to stoop eight hours daily over an emery wheel.

In asking you to take this extraordinary interest in preventive medicine and hygiene, I am asking you in all probability to curtail your income from the practice of curative medicine. I doubt if such a request could safely be made of any other profession without fear of ridicule, or perhaps personal violence. To your credit be it spoken, I do not think I am in danger of either. I confidently expect that in the future, as in the past, the physicians of Massachusetts will recognize their moral obligation as health officers and teachers of preventive medicine, and continue to aid health officials in reducing death rates in the Commonwealth.

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF THE EFFICIENCY EXPERT.*

By FRANK B. GILBRETH, PROVIDENCE, R. I.

IN order to describe what an unprejudiced and trained observer in the field of waste elimination thinks of the hospital problem, and what method of attack upon it he would advocate, it is necessary to state what an efficiency expert does, and also to state what hospital efficiency is, from the standpoint of waste elimination.

An "efficiency expert," so called, is simply an engineer who substitutes accurate measurement for personal opinion, judgment, and unscientifically derived conclusions; who has devised units, methods, and devices of measurement that enable him to measure and compare the factors of results of problems that confront him. He comes with no ready made conclusions that are results of theory only, but comes, rather, with measuring means for comparing any performance with its plan. You, whatever your interest in the hospital problem, are primarily scientists. You are interested in facts, and the underlying laws the facts illustrate. All science is based on measurement. You know what we owe to science and measurement. The problem resolves itself into this:—How far has measurement been applied to hospital work, and how far have the results been taken as standards for practice; how can we consider the hospital as a factory; what methods of measuring efficiency in the manufacturing establishment are usable in a hospital?

In considering hospital efficiency, there are two questions which must be asked:—(1) "What does this factory, called a hospital, manufacture; what is the hospital's aim; and how is it attempting to attain this aim?" (2) "Are we getting the product as cheaply, as quickly, and in as large quantities as is possible?"

To consider the hospital in the most general terms, it must be considered as a "happiness factory." The hospital is subject to all the laws and processes of obtaining efficiency in the manufacturing establishment. The output of the hospital is "happiness minutes;" the aim of the hospital is to give the largest number of units of happiness to the most people, with the least expenditure of time, money, and effort,—or, in other words, with the least expenditure of energy possible.

We must think of this product, happiness, (1) as of the happiness of mankind as a whole—of the social group—(2) as of the individuals comprising the group. The happiness of the social group will be best gained when each individual in the group is happy, and when all are working together for the good of all. In the factory, this condition is called "heartly

* Abstract of paper read at a meeting of the Suffolk District Medical Society on January 6, 1915.

coöperation." It is one of the nine fundamental features of measured, functional management.

There is nothing corresponding to this in the management of any of the scores of hospitals that we have surveyed. The problem is not one of medicine or surgery. It is a problem of management. If you do not agree with me, I suggest that you write down what you think the purpose of a hospital is. It is not important that we agree, today, as to what the fundamental aim is. It is important that the aim be determined accurately.

The next question is, "Are we getting what we are aiming for?" Individual surgeons and hospital superintendents have said, "Yes." But if we are, have you so formulated your results that others may use them to transfer skill, and improve upward from the results of the most successful? If your hospital force is getting what it desires, how about the individuals comprising the group? Each individual is most efficient when he does what he can do best, and likes most, for the greatest percent of his time possible. The social group is most efficient when its every member has been assigned functionalized work.

No hospital has as yet submitted its aims and methods to accurate measurements. Most hospitals have not put that work which they have done in such form that it can be effectively used.

To apply accurate measurement,—first of all, apply the survey principle. Record *what* you are doing, *how*, and *why*. The first step in all improvement is an accurate record of present practice. But where is there such a record of hospital practice? We have been trying for three years to get some surgeon to write a detailed account of an operation.

The next step is applying measurement to the records. Such measurement is technical work. It demands an understanding of the fundamentals of management. The various tests which have been worked out, and which apply to capacity of all sorts, must be applied. The likenesses that underlie all lines of activity must be realized. It has been customary always to emphasize the difference between things. We look for likenesses as well as differences. The great fundamental, underlying all lines of activity, is the fact that it is human activity.

What we propose to you is that you learn to think in the industrial vocabulary,—to use industrial experience. The industrial world has been obliged, through economic pressure, to study waste elimination. It has derived underlying laws for attaining least waste, underlying methods for applying these laws, and an equipment of units, methods, and devices of measurement. You, with the greater need, education, field, and work of greater importance,—can gain results from measured functional management, the magnitude and far reaching effects, of which no industry could hope to equal.

You have but to see and accept the necessity

for measurement. What has been done in the industries is at your service. You, as individuals, can take these results, and work at your own problems; but the big things demand coöperation. Functionalization, inspection, standardization, the right incentive, the proper teaching, the least fatigue, the greatest welfare,—these are the results. At the root of them all lies *Measurement*. Time study, motion study, the chronocyclegraph and micro-motion processes,—these are means of making measurements that lie ready to your hand. The great question to be answered is, "Shall we make the hospital a place fit for scientists to live and work in; shall we submit our work to measurement, and act on the results?"

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF A HOSPITAL SURGEON.*

BY R. L. DICKINSON, M.D., F.A.C.S., BROOKLYN, N. Y.

Capable of standardization are:—

- 1—The training and qualifications of the workmen and heads of departments—doctors and nurses—even trustees.
- 2—Tools and equipment.
- 3—The organization of the workshops—office and hospital and sanitarium.
- 4—The procedure.

Many of the factors are being worked out:—

- 1—A. Among professional men—
 - a Preliminary education,
 - b Medical education,
 - c House staff service,
 - d Dispensary service,
 - e Assistance in hospital,
 - f First assistant positions,
 - g Heads of service or full attending,
 - h Consultants.
- B. Among nurses:
 - a Training in school.
 - b Training in hospital.
 - c Training in operating room.
 - d Training in social service.

But the status of the interne is chaotic: in one place he is a mere dresser; in another, he demands laparotomies—and with no more preparation; the attendings are responsible to no one; the consultants do not consult or advise or inspect; many trustees take it out in trusting. How many real advisory boards, like that of the Rockefeller, are in active existence? Among nurses why should peritonitis be risked to give

* Read at a meeting of the surgical section of the Suffolk District Medical Society on January 6, 1915.

every nurse a bare smattering of training to be head of an operating room, any more than house officers be given the impression they can do major surgery?

2—As to *tools*, we have not made a start to standardize such things as:—

- a Form.*—For example, with the needle why should the stitch ever slip out if the eye is wedge-shaped? Or why should a cutting edge needle ever be used except for skin or cervix? Or a flat portion, for grasping, be missing in needle holder?
- b Material.*—Why should some needles be brittle?
- c Number.*—Why should the group working in an operating room not agree on a few fixed forms and sizes?
- d Name.*—Why should not all operators call one tool by one name?
- e Price.*—Why not an average cost?

3—As in the organization of the workshops, whether it be the private office of the family practitioner, the group in an office building, the dispensary, the private hospital, the public hospital or the sanitarium, only the beginnings have been made for standardizing professional work. The appended references will give the clue to these beginnings and the outlines that follow are mere skeletons or samples of the kind of planning that is inevitable in the near future.

4—As to the procedure, there is no frequently repeated act in hospital work, from the taking of histories up to the team work in the gravest operation, that cannot be plotted out to standard made up from a study of the best methods, and printed on instruction cards. It goes without saying that adaptation is made to fit varying needs as, for instance, to the little hospital in a small town or the great public institution.

THE FIVE INEFFICIENCIES (IN PROFESSIONAL WORK).

1. *Lack of Time* given by staff because free hospital work is necessarily secondary to earning a living in all but exceptional cases.

Remedy.—Requirement of fixed hours and quality of work, for salary; selection and promotion for merit; service continuous; ratings and reports on amount and character of product; assistants with some salary, and in sufficient numbers; senior resident a hospital graduate, remaining two or more years on salary.

2. *Lack of Organization.*

Remedy. — Single-headed departments; small committees, held to strict responsibility; certain changes in allotment of functions or parts of the work, in accord with the ideas of "Scientific Management"; understudy for every position;

associate in full charge two months of each year; long time team-work in operating room; short time internes to do only minor surgery.

3. *Lack of Instruction.* Nobody's business to see that men are drilled in technic and duties; no instruction cards.

Remedy.—"Vorschrift" throughout, and definite methods and times of teaching and drilling younger men.

4. *Lack of Inspection.* No check on quality of work or end-results.

Remedy.—Study of product, and delegation of one man (or several) to duty of frequent inspection and recording of details of technical work, and report of same to governing board.

5. *Lack of Publicity.* No bulletined errors; no available comparisons.

Remedy.—Inspection, tabulation of successes and failures, study of end-results and ratings on work of each department and each individual, and publication of same, particularly in state and municipal institutions. Publication need not involve great bulk. An interval appendectomy with prompt healing takes but one line. Cases that do badly call for detail.

SUGGESTED FORM OF REPORT ON EFFICIENCY OF EACH MEMBER OF PROFESSIONAL STAFF.

Position held. Average No. of beds.

- A. *Quantity of work*; months on duty; total visits required; total visits made; total hours given to hospital (or dispensary): vacation; illness; absences, excused, unexcused.
Estimated committee service.
- B. *Quality of work*; (thoroughness, promptness, rapidity).
 1. Preliminary examinations, consultations.
 2. After-care, examinations for discharge, instructions to follow-on.
 3. Histories, personal inspection, personal notes, reviews, studies on end-results.
 4. Laboratory work, supervision, personal work.
 5. Training of hospital staff, nurses, dispensary staff.
 6. End-results (Codman methods); each individual's errors scored by
 - a. lack of technical skill;
 - b. lack of surgical judgment;
 - c. lack of care or equipment;
 - d. lack of diagnostic skill.

Failures grouped also by:

 - a. patient's enfeebled condition;
 - b. patients' unconquerable disease;
 - c. patient's refusal of treatment, and by
 - d. surgical calamities.

Methods; notes on full histories by chief; review by consultant or efficiency committee; summary of history by clerk; choice by staff of certain operations as tests (e.g. suppuration in clean laparotomies).
- C. *Personality*; integrity; disinterested obedience to rules; team-play; kindness; cheerfulness; enthusiasm; and ability to inspire these.
- D. *Progressiveness*; study of literature; travel to other clinics; membership and attendance at medical societies; originality; researches; publications.
- E. *Executive ability*; initiative; originality; organizing power; control.

- F. Teaching*; staff, nurses, dispensary; students; public clinics.
- G. Inspections*; number, by trustees, consultants; hospital inspector. Certain defects to be heavily scored—such as lack of judgment. Percentage to be given under each heading to be determined. Positions differ. Some positions will have a score for executive work, and some for teaching and others will not. This will involve grouping and reporting such positions separately, but any man's abilities in the above matters should be noted, even if not marked on a score.

COMMITTEE FUNCTIONS.

- Efficiency Committee, ECm.* Member board of trustees, member of staff, superintendent; reviews of order of work, equipment, instruction, time and cost and results.
- Professional Staff Committees.* One man each, chief or associate; with substitute, one of younger men (except ward committee).
1. *House Staff, HSCm.* Finding internes, provision of instruction, report on quantity and quality of work done by each, but superintendent has executive control.
 2. *Operating Room, ORCm.* Harmonizing and standardizing equipment, procedure, and lists (instruction cards).
 3. *Ward, Wcm.* Diets and drugs and formulae; nursing (instruction cards).
 4. *Histories, HCm.* Also library; publications; standard nomenclature of diseases, injuries and operations; filing, indexing.
 5. *Dispensary, DCm.* Professional relations and nomination, but dispensary has its own meetings, and joint clinics; its executive control under the assistant superintendent.

Planning.

- a Committee on Order of Work, OWCm.* May be chiefs from three main services, with superintendent and senior resident; chairman, chief surgeon.
- b Committee on Instruction Cards, ICCm.* May be five staff committee men, plus superintendent and senior resident; chairman, history committee man.
- c Committee on Discipline, DCm.* Same as OWCm. Chairman, superintendent.

DEFINITION OF DUTIES (SAMPLE).

Operating Room Committee. Symbol—ORCm.
TASK:—

- a To gather ideas and information pertaining to equipment, routine, standard names of tools, in other clinics, and submit improvements to the surgical staff, with recommendations.*
- b To prepare, to submit to surgical staff, and when endorsed, enforce, for average conditions, a standard or minimum procedure, in sterilization, preparation for operation in general and for particular classes of operation, in team-work at operations, etc.*

- c To secure agreement among surgical staff as to standard equipment, (e.g. knives, sutures, and material).*
- d To order new equipment and repairs for O.R. outfit.*
- e To recommend to staff candidate as anesthetist and arrange for anesthesia.*
- f To oversee O.R. nurse's methods, cataloguing, entry in book.*
- g To arrange with instructor for drill in technique of the specialists, associates, and assistants.*

PERSONNEL:—Member of surgical staff (preferably chief or associate); substitute to act in his absence, younger man on surgical staff.

METHODS:—

- a Instruction of professional staff and house staff and O. R. nurse as to routine of O.R. (or deputizing same).*
- b Assignment of studies in O.R. technique to members of staff.*
- c Report to staff meetings (in writing, for annual report).*

EQUIPMENT:—

- a Operation book.*
- b Card catalogue of instruments, with cut of each, under standardized names.*
- c Standardized samples of needles, gut, etc.*

In order to take up the whole subject of the efficiency of the hospital and its professional work in a far-reaching manner, which will prevent duplication of effort and provide for combination and coöperation, the following would seem to be required:—

First, a *Central Board on Standards*, whose function it should be to collect information and sift it, to allot the parts of the great problems for investigation, to furnish means for some part of the necessary research, to publish the results, and in general to serve as a board of control. Such a board might well be a committee named by the American Medical Association in conjunction with the American College of Surgeons. Its various functions only experiment will determine, but travelling instructors with sample outfits and regular inspection may well become part of its extension work.

Second, *Experiment Stations*. These may be in a variety of locations and institutions, duly accredited, as in our best research laboratories that are connected with active clinics.

Third, a *Library*. This should be central, with branches and the utmost facility for loaning books—very much as the Surgeon-General's Library does it, or it might be a branch of this library.

Fourth, a *Museum of Standards*. This, too, should be central, as in Washington or Chicago, and should have certain facilities for loaning standard outfits.

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF HOSPITAL TRUSTEES.*

BY WALTER WESSELHOEFT, M.D., CAMBRIDGE, MASS.,

Trustee of the Massachusetts Homeopathic Hospital.

IN speaking as a trustee on the question of efficiency I must keep in mind the position so far held by the boards in relation to the hospital staffs. Their responsibility is for efficiency in administration, which is distinct from efficiency in the wards. This latter the trustees must take for granted. The people whom the trustees represent take it for granted. The question is, are the trustees in any way prepared to keep a watchful eye on the efficiency of the staffs? Is it called for and is it possible?

The trustees would be treading on very difficult and very delicate ground in case they were to propose new measures or methods. For it must be borne well in mind that the introduction of efficiency does not mean the introduction or control of the methods in use. It means much more. In point of fact it means the application of the *method of science to therapeutics*, in other words, to clinical research, and this means the methods for the *elimination of error and of comparative therapeutics*.

I believe that sooner or later the profession will wake up to the need of this reform; but for obvious reasons the trustees cannot be asked to introduce innovations of so far reaching and difficult a nature. If they can be made to see the importance of this method, and the results sure to follow in time, they will not fail to give it all the support in their power, but the first

steps must come from the profession, and it must be made plain that they include no courses of idle individual experimentation.

Certain features, I believe, might be established with comparatively little difficulty or expense, and it is this latter which the trustees have to watch over with care. It might be practicable to institute means for determining *end results*. Accurate records and certain extensions of the social service, a part of many hospitals, might accomplish this. In surgery with its allied branches, early results might be made to appear.

In internal medicine, however, the difficulties would be infinitely greater. Here we are confronted at the outset by the fact that diseases recover under all sorts of treatment, that they recover under no treatment at all, and that they terminate fatally under the best treatment, or that which is accepted as best by any individual party or school. Again, the present methods for meeting our responsibilities have been fitly described, not so long ago, "as a jumble of contradictory rules and expedients originating in part in shallow and illogical generalizations and in part in crudest empiricism."

These two propositions placed in juxtaposition constitute a chaos out of which no board of trustees can extricate us. There is but the one remedy in sight, the framing of rigid rules and their *faithful observance* both of *control* and *record*, to which should be added *continued service*. By these means many errors might be eliminated, many a doubtful course replaced by a better one and the rising generation drilled in the art of observation which now leaves much to be desired. It would mean a mighty reform in therapeutics and by the comparative method, minimize the effects of the personal equation of the individual physician, and establish in time the merits of old and new methods. The scientific method, that based upon the fundamental principles of science, is no mere generality. It is the sole umpire between opposing measures and methods. So long as doctors differ (and in our hospitals as elsewhere, they will always claim the right to do their best in their own way) there must be found a way of differentiating the better from the good and the good from the bad.

It would lead one too far to enter upon a discussion of details. These must come from other quarters. There can be little question that a reform to which the profession is ready to devote its energies must succeed.

Let me briefly add a further reason why in time this reform should succeed. Here in your security, where you are constantly listening to the best that can be brought before you, you are apt to forget that with all your power and influence, you and we, as trustees, represent only a part of the people; that a very large portion of them are left as free to form an opinion on medical subjects as they may on subjects of religion. Conse-

* Read at a meeting of the Surgical Section of the Suffolk District Medical Society, on January 6, 1915.

quently before the law we occupy no other position than that of other systems, theories and methods not recognized by the profession. The law-making powers are willing to grant your prestige and preëminence and are willing to give you a free hand in matters pertaining to the public health, but you know them to be quite as willing to bestow their favors as generously upon any body of practitioners coming before them to demand a charter or claiming miraculous powers of healing. This is the infinite advantage of a free country, but it throws a double responsibility upon the profession.

THE RESPONSIBILITY OF THE GENERAL PRACTITIONER FOR THE CARE AND SUPERVISION OF THE DISCHARGED SANATORIUM PATIENT.

BY JOHN B. HAWES, 2D, M.D., BOSTON.

IN considering how far the general practitioner should hold himself responsible for the care and supervision of discharged sanatorium patients, I am assuming at the outset that every tuberculosis patient at some time or other should have the training that the sanatorium alone can give. Although Dr. Charles L. Minor of Asheville and Dr. Joseph H. Pratt of Boston have done much to show us what real home treatment is and what it can accomplish, most of us feel that home treatment should never take the place of sanatorium treatment except in the rarest of instances. In many states, far too many, unfortunately, home treatment is the consumptive's only resource; in Massachusetts, however, this is not so. Although there are not yet in this state as many beds as there should be, there are enough so that nearly every patient who needs, and who seriously desires sanatorium treatment can get it. It is true that often the patient has to wait one, two or three months or longer before admission, which is, of course, a serious obstacle to effective treatment of early cases. If this interval, short or long, can be bridged over, the patient can be sure of receiving high class sanatorium treatment at little or no cost and, with the exception of Rutland, for as long as he chooses to remain at the sanatorium. There are about 3000 beds for consumptives in Massachusetts; of these, nearly 1000 are in our state sanatoria, 750 in other state institutions, about 1000 are in local tuberculosis hospitals, and 250 are in private sanatoria and hospitals. At Rutland we can accommodate all the incipient and early cases who apply. By a new arrangement, whereby each patient entering this institution is placed on a month's probation as it were, to

determine whether or not he or she is really an incipient or favorable case, we expect to greatly increase the percentage of early cases at this institution. Last year the proportion of incipient cases was 37%, the largest in the history of Rutland. Of special importance, we hope to reduce the time that patients now have to wait after applying and before admission. While we still take many far advanced patients at North Reading, Lakeville, and Westfield, we hope, as the number of local hospitals increases that these institutions, too, will be used to a far greater extent than now in caring for those patients who, if not incipient, are at least only moderately advanced and are favorable for marked improvement or arrest. The incorrigible consumptive still presents a most difficult problem. It is one, however, that must be settled in most instances by local and not state authorities.

At the present time there is a strong feeling prevalent, not only in this country, but in Europe that the sanatorium and the sanatorium treatment of consumption is on trial; that it has not proved the great success and brought about the results which we hoped that it would. Literature is filled with articles bearing the titles, "Are Sanatoria Worth While?", "Home versus Sanatorium Treatment," etc. This is a situation which we must face; the reasons for this doubt and mistrust must be clearly analyzed and understood by all if we hope to improve the situation.

I believe the great and fundamental reason why there is a growing doubt in the minds of the public and the medical profession that the sanatoria have not turned out to be all that they should, is because of the lack of early diagnosis and aggressive treatment on the part of the medical profession. The early diagnosis of tuberculosis, however, and the reasons for the lack of such diagnosis, is a subject far too large to be considered within the scope of this article.

The other great reason for this state of affairs is because the average general practitioner has not realized sufficiently clearly that his duty toward his patient is not ended when he has escorted him safely within the doors of a tuberculosis hospital or sanatorium. He does not realize that the time spent at the sanatorium is merely preliminary to years of faithful treatment on the part of the patient and constant and wise supervision on the part of the doctor after the patient leaves the sanatorium. If every general practitioner would only realize this, and constantly remember that the time spent by the patient at a sanatorium or health resort is simply an incident in his course of treatment, the important part of which must come during later years, our results would be far better. It is the constant throng of patients who have relapsed and who make re-application for admission to our institutions, generally in a worse condition than they were before, which makes not only them and their relatives, but the

general public, ask what good has the sanatorium done in their case. It is very true that much of the blame for this state of affairs rests with the patients themselves. A certain part of it, however, we members of the medical profession must assume. The sooner we assume it and take steps to correct it, the quicker will the public follow in our footsteps. At the present time it seems to me that the State as such is going as far as it well can under existing conditions in looking after its discharged sanatorium patients. Our present system, already familiar perhaps to many of you, is somewhat as follows:—

On receiving a patient's application at the Boston office, the physician is at once notified as to the sanatorium to which his patient is to be sent. On admission to the sanatorium some time later, the physician and the local board of health are again notified. Finally, on discharge from the sanatorium, the physician is written a personal letter giving in considerable detail the patient's present condition with advice for the future. The two following letters were taken at random from our files:—

"March 20, 1913.

"My dear doctor: E. C. was admitted to the Rutland State Sanatorium December 9, 1912, on an application made out at the Boston Consumptives' Hospital. He was discharged March 19, 1913.

"He was admitted as an incipient case of pulmonary tuberculosis, and was discharged with the disease 'arrested.' At the time of admission there was slight dulness to the third interspace, at the top of the right lung, and a few fine râles, both front and back. At the time of discharge there was suspicious dulness at the apex, but no râles were heard. The patient seemed to be in excellent physical condition, and I believe he will be able to take up some clerical work, such as he had been doing, and if he uses reasonable precautions he will probably be able to live very well in Boston.

"I advised him to return to your clinic to be examined occasionally."

"July 3, 1913.

"Dear Doctor: This is to inform you that Mr. J. B., admitted to this sanatorium July 1, two days ago, absconded at 7 a.m. today. He is a 'moderately advanced' case of pulmonary tuberculosis, expectorating about two ounces of sputum per twenty-four hours, in which tubercle bacilli are exceedingly abundant. He has vesperal fever and other signs of marked disease activity.

"As far as can be learned, this patient said that he left the institution because he did not like it here. He told the patients that he wanted to get out to celebrate over the Fourth.

"This patient has not been in the institution long enough to show any improvement, but he has shown that he needs treatment immediately, and isolation from healthy people, as he is, no doubt, a very infectious case."

Copies of such letters are sent to the local board of health, the local anti-tuberculosis association, if such there be, the state board of health, and to this office. Within the course of a few weeks after discharge, this patient is vis-

ited by Miss Billings, our nurse engaged in this after-care work. Miss Billings makes a detailed report of the patient's condition, surroundings, family, occupation, etc.; and of still more importance, whenever possible, becomes a friend of the family, personally interested in the patient's affairs, and not merely a paid emissary of the state. In addition to this, she sees the local visiting nurse or someone connected with the local board of health, or the patient's physician, if such there be, and makes suggestions as to future needs. Some months later another visit is made if necessary. Whenever possible, Miss Billings gets in touch with the local nurse or tuberculosis worker and turns this work over to her. This is as it should be, for, after all, it must be realized that tuberculosis is a local problem, one which commences and ends at home.

I do not see how the state can go further than it is now doing, as I have described above. The burden of the rest of the work must be assumed, first by the local boards of health, tuberculosis societies and dispensaries, and last, I believe, of still more importance, by the general practitioner.

Local boards of health are not yet doing all that they should in this matter. While the advisability of forcing every city and town which comes under the terms of the "Isolation Hospital Act" of 1910 to build a local tuberculosis hospital may be open to debate, there is absolutely no question as to the wisdom of the law requiring towns and cities of 10,000 inhabitants or over to maintain a tuberculosis dispensary. I have every reason to believe that our present state health commissioner is to take immediate and urgent measures to see that this law is enforced and that dispensaries coming up to a certain standard are established in every town or city coming under this act.

The establishment of such dispensaries will greatly increase the efficiency of this after-care work that Miss Billings is doing and will lead to far closer coöperation than now exists between state and municipality. To be really effective, however, every doctor should aim to do for his own private patients exactly the kind of work that is accomplished by a properly run dispensary. In other words, he must not only diagnose tuberculosis in its early stages, and steer the patient to a hospital or sanatorium, but he must look after the patients when they return from the sanatorium.

We believe that this after-care work of Miss Billings has accomplished a great deal during the last two or three years that she has been in our employ. The number of people over whom the influence of this after-care work extends is far greater than the actual number of patients whom she visits. For instance, between July, 1912, and October, 1913, a period of fifteen months, Miss Billings visited 600 patients. These 600 patients, however, had exposed 2601 others; 23% of these were examined for tuber-

eulosis, and of these 12½% were found to have consumption. The first 200 patients in this group, whom she visited early in her work, beginning in July, 1912, had exposed 871 others. Of these it was found that 20% had been examined and that 14% had consumption. While the last 200 patients whom she visited up to October, 1913, had exposed about the same number of others, 824, Miss Billings found that 30% had been examined for signs of tuberculosis, instead of 20% in the first group, and that only 5% were found to have consumption, in place of 14% in the earlier group. This improvement, though slight, is certainly encouraging.

Every physician will at once ask, "How am I to get hold of my patients after they are discharged from the state sanatoria if of their own accord they do not choose to come to me?" I believe that the medical profession must do away with a certain amount of false pride which it now has in seeking out these patients. I believe that the time is at hand when doctors should do more than wait until these patients come of their own accord to their offices, and that they must take some active steps to see that their discharged patients report soon after their discharge and continue to report later on as often as is considered necessary. This certainly is in accord with the attitude of the life insurance companies, certain of which are now demanding that their policy holders be examined once or twice a year regularly, whether they are sick or not. As a general thing, I think that the average tuberculous patient on discharge from any sanatorium should report at once to his local physician, once a month regularly for at least six months, and once every three or four months for two or three years afterwards. I demand this of all my private patients. If this were done as a routine and the need for it explained to the patient, I am sure it would be one of the best investments ever made, not only by the patient himself, but by the state of Massachusetts.

Miss Billings has given me some interesting figures on this subject, based on a study of 100 patients having family physicians, taken at random from those she has visited from July, 1912, to December, 1914. Of these 100 patients, she found that 46 had been examined by their physician on their return, and that 54 had never been so examined. Of the 46 who were examined, 32 saw a physician within the first month after discharge, and 14 later on. Of the 54 who did not see a physician, 22 did not do so because of ignorance or because they did not think it worth while; 22 did not go to see a doctor because they were waiting for some symptoms to arise to make it necessary. These 22 represent the large class of the public who apparently feel that it is better to wait until they are actually sick before seeing a physician, instead of using his services in order to keep from becoming sick. Ten of the 54 patients did not go to their doctors because of

lack of funds. Miss Billings has further subdivided these 100 patients into two groups, the first consisting of 50 patients visited early in 1912, and the second 50 composed of those visited late in 1914. The comparative figures are of interest. Of the first group which she saw early in 1912, 17, or 34%, were examined by a private physician after their discharge; 25% of these, within the first month after discharge, and 8% later on. Of those who did not go to see a doctor, 48% were awaiting symptoms, in 18% it was on account of ignorance, while in no instance was lack of money the reason for not consulting a physician. In the last group of patients whom Miss Billings saw late in 1914, 29, or 58%, were examined by their private physician, and of these 38% within the first month after discharge. Of the 21 patients who did not see a doctor, in only 9, or 18%, was ignorance the reason. In only 4 instances did the patient give as his reason for not being examined, the fact that he had no symptoms; while 10, or 20%, gave financial difficulties as the cause of their not consulting a doctor.

TABLE I.

FIFTY PATIENTS VISITED IN 1912.

Examined by a private physician	17—34%
Patients examined during first month after discharge.....	13—26%
Patients examined after the first month after discharge.....	4—8%
Of patients who did not see physicians there were.....	33—66%
Awaiting symptoms.....	24—48%
Ignorance.....	9—18%
Financial difficulties.....	0—0%
Total	50—100%

TABLE II.

FIFTY PATIENTS VISITED IN 1914.

Examined by a private physician	29—58%
Patients examined during first month after discharge.....	19—38%
Patients examined after first month after discharge.....	10—20%
Of patients who did not see physicians there were.....	21—42%
Awaiting symptoms.....	2—4%
Ignorance.....	8—16%
Financial difficulties.....	10—20%
Total	50—100%

The difference in the figures given in these two groups of cases is marked and shows a most encouraging improvement. Of course it must be realized that the patients whom Miss Billings visits are only a small group of the whole number of consumptives in this state.

This after-care work which Miss Billings is doing should be carried on in every community by nurses, dispensaries, and private physicians. In no instances should lack of funds be an adequate reason for the patients not being exam-

ined. Ignorance as a cause for such lack of supervision and advice after leaving a sanatorium, must be combated by an educational campaign and everywhere the general public must be made to realize that it is far better to spend a little money to prevent sickness than it is to wait until some disease gets a firm grip on the system before consulting a physician.

I feel that the public, as a result of our own efforts, is apt to think too lightly of tuberculosis and to regard it as too easily curable. Ten or fifteen years ago, when Massachusetts was making its first efforts to stamp out tuberculosis, we used the slogan "tuberculosis is curable." This was necessary in order to do away with the pessimism which the name "consumption" had hitherto inspired. At present I feel that we have gone a little too far, and that we must qualify this statement and impress upon the public and upon our patients, that while tuberculosis is curable, it is the most chronic of all chronic diseases; that it is rarely curable in any period under one year, and that the term "arrest" rather than "cure" is a far wiser one to use. It would be an excellent thing if every doctor in this state would impress this point of view upon his patients.

Finally, then, the important points to be borne in mind in regard to this subject are:—

1. Every tuberculous patient at some time or other needs sanatorium treatment.
2. The doctor's responsibility for his patient does not end as soon as he has safely conducted him within the doors of a sanatorium or other institution.
3. The important period in the treatment of the average case of pulmonary tuberculosis is after the patient has left the sanatorium.
4. The medical profession, either by means of dispensaries or other similar agencies, or in their private practice, must *seek out* their discharged sanatorium patients and see that they are under proper supervision and control.
5. Every doctor should play a part in a broad educational campaign to impress upon the public the need of such supervision and control.

TUBERCULOSIS OF THE THROAT.

BY ALBERT C. GETCHELL, M.D., WORCESTER, MASS.,

Consulting Laryngologist of the Massachusetts State Sanatoria.

THIS paper is mainly a report of the work of the four Massachusetts State Sanatoria for the year 1914. It has taken this form because the material is too abundant to be properly handled in the space allowed for it in the regular yearly report of the Sanatoria, and because in this manner the results of our experience there may be of most use to the medical profession.

The resident physicians of the sanatoria have examined the throats of all the patients under their charge and have recorded the results of these examinations. They have conducted treatment and have done such operations as, under the supervision of the superintendents, they felt competent to do. I have visited each institution regularly for the purpose of supervising the work, for consultation in individual cases and for such operations as were needed. I have also visited them at other times for special cases.

The cases may be divided into two classes, those at Rutland which in the main are earlier cases, and those at the other three sanatoria which embrace cases in all stages, the advanced cases preponderating. It is to be noted that while it is the policy of the management of the sanatoria to reserve Rutland for early and favorable cases it has not been possible hitherto to completely do this. Not only do advanced cases obtain admission but other cases become advanced while there and up to this time several of these cases have remained in the institution.

At Rutland out of 825 patients treated during the year 38 or about 4% had tubercular involvement of the throat, in all cases the process being limited to the larynx or epiglottis. The epiglottis was involved in 7 cases.

At North Reading out of 522 patients treated 39 had throat involvement; at Lakeville out of 725 treated 85 had throat tuberculosis; while at Westfield only 15 cases out of 488 treated had throat disease, this small proportion at Westfield being due to the fact that of this 488 treated 207 were under 16 years of age, not one of whom had any tubercular throat lesion. With the exception of the children at Westfield all these patients were of the same class and so they may be grouped together.

Of 1488 patients treated at North Reading, Lakeville and Westfield, 139 or about 9% had tuberculosis of the throat; of these 23 had involvement of the epiglottis and 6 of the pharynx.

Of the *Westfield* cases 1 improved, 7 remained stationary and 7 died.

Of the *Lakeville* cases 23 improved, 19 were unimproved and 23 died.

Of the *North Reading* cases 9 made substantial improvement, 18 were unimproved and 12 died.

Of the *Rutland* cases 24 either entirely recovered or showed marked improvement, 5 were stationary, 5 were recorded as progressive and 4 died.

Generally speaking, these figures show that tubercular involvement of the throat is a terminal stage of pulmonary tuberculosis, for in no case was a throat lesion found where there was not previous pulmonary disease. But this is by no means universally true, for laryngeal involvement may occur in any stage of the disease. It might be noted here that of 1180 patients who have come under my observation at the tuberculosis clinic at the Worcester City Hospital I

have noted 60 cases of probable tubercular laryngitis. It is to be observed that these were not all tubercular persons but were those who came for examination for suspected tubercular disease.

That marked tubercular involvement of the larynx is not incompatible with prolongation of life is shown by one patient at Westfield. This man is now 60 years of age. In 1904 he was operated on twice at the Massachusetts General Hospital, once for removal of an interarytenoid growth and once for removal of the right arytenoid. Tubercle bacilli were then found in his sputum. Now he has extensive involvement of the left side of the larynx—arytenoid and ventricular band—of a rather dense whitish variety. It does not have the edematous look of active tubercular disease but more of the chronic type. He is now in a fairly good state of health, and as he is a good gardener, Dr. Chadwick is counting on his valuable services in next spring's work.

DIAGNOSIS.

How can we determine the existence of tubercular laryngitis? No symptom is proof positive of it. Hoarseness or pain occurring in a tubercular person is strong presumption of tuberculosis of the larynx but both these symptoms may be present and due to other causes. On the other hand tubercular disease may be present in the larynx and both these symptoms be absent. Positive proof is found only by direct inspection of the larynx. Limited or general infiltration of laryngeal tissues with or without loss of tissue, ulceration, in a tubercular person is proof of the tubercular involvement of the larynx, always bearing in mind the possibility of the co-existence of syphilis. Exception should be made for that irregular papillary thickening between the arytenoids which persists for indefinite periods with no change and also bilateral enlargement of the ventricular bands, not of one band, however, which is probably always tubercular.

I would again like to record our experience that tubercular invasion of the larynx is not accompanied with pallor but on the other hand with redness.

TREATMENT.

The treatment of throat tuberculosis is par excellence what is known as "sanatorium treatment." Tuberculosis of the larynx is a local manifestation of a disease process, more or less widely spread, and always, in our experience, preceded by and associated with disease of the lungs and at times of other organs of the body. Improvement of the local condition is dependent upon the same factors which bring about improvement in the general condition. Local treatment has its value but it must be applied with careful consideration of general as well as local conditions for it may defeat its own ends, not

only increasing the local activity but also adding a too heavy burden to the already overtaxed system.

To formulate our ideas into a working scheme of treatment we divide the disease into three classes: (1) those cases where the larynx is invaded by disease which is also active and progressive in the lungs; (2) those cases where the larynx is involved but the lung lesion is either stationary or moderately progressive, and (3) those cases of terminal disease in which both laryngeal and lung conditions are actively and disastrously progressive. In all cases rest of the larynx as complete as possible is of prime importance.

The Rutland doctors note in the description of their cases "absolute silence" which they are pretty well able to carry out because the patients expect to get well and the whole regime of the institution is based on that idea and so the co-operation of the patient is willing and constant.

In cases of the second class the remedy is as important but more difficult to apply, because the patients feel pretty well but also because as a class they are not so hopeful of ultimate cure, and have not the stamina to put themselves to the inconvenience of enforced silence. Thus Dr. MacCorison at North Reading says "Resting the throat so far as voice is concerned seems to be the most efficient remedy but the most difficult to get patients to carry out. Excessive use of tobacco, with or without fire, has its deleterious effect upon tubercular throats."

In cases of the third class, patients are too sick to talk and moreover talking is apt to be so painful that they voluntarily desist.

In local treatment many medicinal agents have been used, viz.: Dobell's solution, Dobell's with formalin, Dobell's with rose water, steam inhalations of eucalyptol, tincture of benzoin and menthol; argyrol 5% to 10% as spray or application; formalin 1-8%; liquid petrolatum; liquid petrolatum with menthol; lactic acid; Lake's mixture; scarlet red 2% in oil; intra-tracheal injections of guaiacol, menthol in olive oil, guaiacol, eucalyptol, menthol in saturated solution of idodoform in ether; orthoform; heroin 2% solution; cocain 2% solution; novocain 5% solution; tuberculin; injections into the superior laryngeal nerve of alcohol 8%; or of eucain 2 grains in one ounce alcohol 80%; or of quinine and urea hydrochloride; also ice bags and counter irritants to the outside of the throat and surgical measures designed to destroy or remove diseased tissue, such as galvanocautery and cutting out of tissues.

It will be seen that many of these agents apply to any form of laryngitis, specific or non-specific, so that in our summary of what we find distinctly useful in tubercular disease we will leave out such.

It is a matter of first importance to keep the larynx clean and free from sticky mucus and

for this purpose we have found nothing better than Dobell's solution. Dr. Lyon, at Rutland, combines rose water with this in the proportion of one drachm to four ounces. Lactic acid and formalin still hold their place for their action upon tubercular ulcers. They are combined in Lake's mixture which consists of formalin, 7 parts; lactic acid, 50 parts; glycerine, 20 parts; water to 100 parts. Menthol in liquid petrolatum, five grains to the ounce, makes a soothing spray and Dr. Burns finds liquid petrolatum freely used very useful in extensive pharyngeal and laryngeal ulcerations. In cases where the trachea is inflamed and especially when it is covered with sticky mucus, intrachel injections are of great value; guaiacol 80 minims, menthol 80 grains, sterilized oil one ounce or guaiacol 9 parts, eucalyptol 2 parts, menthol 1 part in a saturated solution of iodoform in ether up to 100 parts as used by Dr. Lyon.

Tuberculin is used in all of the sanatoria. It has no special efficacy in throat cases.

Pain we have not found to be an important symptom unless the epiglottis is involved and then it may be very distressing. For this we have used orthoform lozenges, a spray of 2% solution of cocaine before eating or a tablet triturate of cocaine, 1/12 grain laid on the back of the tongue. In extensive involvement of the larynx and epiglottis with ulceration I have found this powder useful,—paraformaldehyde 1 drachm; orthoform, 1 drachm; compound stearate of zinc 48 grains; cocaine, 10 grains, and sulphate of morphia, 10 grains.

We have used the method of injections into the superior laryngeal nerve with varying success but with enough success to encourage its further use. When we consider the small size of the nerve and how loosely it lies in the tissues it is manifestly difficult to hit it every time, so that it is a procedure where increased experience peculiarly gives greater guaranty of success. The technic is as follows,—after the skin has been properly prepared, to search with pressure of the finger for the spot under which the nerve lies. In a certain number of cases this may be determined by eliciting pain which appears to run toward and to the ear. While it is difficult to locate the exact point in persons suffering from laryngeal disease it can be done upon well persons more readily, so that it is useful to attempt to locate it either upon one's own self or on the throats of friends by pressing above the thyroid cartilage in the space between it and the hyoid bone. In this way one can get approximately the point of entrance of the needle which is plunged into the tissues about one-half a centimeter and a drop or two of the solution expelled. If the right spot is reached the pain running to the ear is evident and then the contents of the syringe is slowly injected although before the syringe is emptied the pain to the ear should disappear.

At North Reading the eucaine and alcohol

mixture was used; one patient had five injections, two of 1 c.c. and three of 2 c.c. Relief followed the first three injections and a repetition was requested but no relief followed the last two. They were done October 9, November 5, 11, 24, and 25; the last note was that patient was in very poor condition but complained little of throat discomfort. Another injection was given December 7; there was considerable relief for a few days but the patient died on January 6. Still another patient was injected on December 7; there immediately followed an increase of subjective symptoms which subsided after a few hours. On December 12 a note stated that the symptoms remained unchanged. On January 15, however, that there had been relief of pain lasting two weeks; the patient died on January 20.

Dr. Chadwick, at Westfield, had, I believe, a similar experience; the symptoms were increased after the injection but later passed away and the relief was sustained for a considerable period. So also did Dr. Lyon at Rutland whose note reads "Injection of 1 c.c. of 80% alcohol in superior laryngeal nerve causing extreme pain extending over a period of four days following which the larynx became completely anesthetized for several weeks." In another patient of Dr. Lyon the injection of 1 c.c. was followed by aggravation of the symptoms for a week. Then 2.5 c.c. of quinine and urea hydrochloride was injected which was followed by complete relief which was maintained for a long period. In still another patient a similar happy result followed, a terminal case which had been unable to swallow without pain for a long time; in this case 2 c.c. of this solution was used.

Dr. Howes, at Rutland, had a similar case; "After injection of 1 c.c. 50% alcohol pain ceased for about an hour and then returned with increased severity. Injection of 1½ c.c. quinine and urea hydrochloride resulted in diminution of the pain."

I might add a case I have had recently at the Worcester Tuberculosis Hospital, a terminal case with extensive lung disease; the larynx and epiglottis were much diseased and there was ulceration in each tonsil. Injection of 1½ c.c. 80% alcohol was followed by relief of the pain and the patient said that what I did "opened up his throat." The relief from pain was maintained until his death several days after the injection.

OPERATIONS ON THE EPIGLOTTIS.

We have operated on the epiglottis four times, to which I desire to add one case occurring in my private practice. Of these Dr. Lyon performed one while I did the other four. Four were complete removal of the epiglottis and one was partial removal of the epiglottis under local anesthesia with the angular punch forceps.

The first operation was on a Rutland patient; a man, 46 years; an ambulant case; the lung condi-

tion was noted as being progressive. There was a tubercular ulceration on one side of the epiglottis and pain on swallowing. On April 27, 1914, I removed the diseased tissue, cutting well into healthy tissue and removing one-half of the epiglottis. Subsequent notes "complete healing followed; all pain disappeared; no recurrence." I have recently seen him and the last statement holds.

The second case was a Westfield case; man about 35; admitted April 9; epiglottis badly swollen; arytenoids injected and swollen; right cord irregular in outline, probably tubercular deposits; marked pain and hoarseness; upper half of both lungs involved; general condition poor. Local anesthetics gave but little relief. Alcohol injections gave considerable relief for about 12 days. I removed the epiglottis on May 30. There was immediate and complete relief which lasted a month when the disease appeared in the pharynx. He died August 8.

The third case was a North Reading patient; admitted May 6, 1914; advanced, bilateral lung disease; left side densely infiltrated; bed case; the epiglottis was infiltrated and there was much pain. The operation was done June 14 and the notes say that there was considerable relief. The patient died September 30.

Dr. Lyon's case was an out-patient at the Rutland Sanatorium; a man of 21 years; lung condition moderately advanced and not actively progressive; epiglottis much involved, also right arytenoid; pain on swallowing very severe. Injection of 1 c.c. 80% alcohol caused marked increase of symptoms; injection of quinine and urea hydrochloride 2-2½ c.c. gave entire relief of pain. After this, on November 15, the epiglottis was removed. At first the patient had some difficulty in swallowing, owing to the absence of the epiglottis, but this soon passed away. At first he was much relieved of his symptoms and he returned to his home in Springfield to await admission to Westfield. February 9, 1915, he was having much pain and difficulty in swallowing and was not likely to live long.

The case that occurred in private practice was of especial interest in showing how pulmonary and laryngeal disease could progress without definite symptoms. Man, married, 53 years, a gardener. He came to me from a neighboring town 12 miles away for sore throat, no lung trouble being suspected by his physician. He said he had always been well except that he had "winter cough" for several years which he did not think of importance enough to see a doctor. When he was 25 his father died of hemorrhage of the lungs. He had worked at his occupation up to two weeks before the time he consulted me. The epiglottis was extensively infiltrated and ulcerated. On careful physical examination pulmonary disease of moderate extent and intensity could be made out in both lungs. Pulse 96, temperature 98.8, loss of weight from 140 to 122 pounds. Considering his previous and recent good health and moderate lung involvement I thought the removal of the epiglottis worth while in hopes that he might be able to eat better and so regain some health and strength. Accordingly, on March 30, I removed the epiglottis. Pathological examination proved the disease to be tubercular. Only moderate relief followed the operation. When the epiglottis was out of the way the larynx was found to be extensively involved. June 8 he was able to come in to see me but was in wretched condition. He died August 15.

It is pretty hard to define any general rule for procedure in these cases. In a general way our experience teaches that when the epiglottis is involved to a limited degree, especially if the lesion is nearer the tip than the base, if the larynx is not involved or to limited extent, and the patient is in fairly good condition then the operation is clearly indicated. It will be noted that one of the patients of this group has at the end of ten months no sign of recurrence and for that period has not only escaped the danger of the extension of the local disease but has been relieved of suffering and inability to take sufficient food on account of pain. The Westfield patient was very grateful for the relief the operation brought and was glad he had it done.

GALVANO-CAUTERY.

I have employed this agent in two cases

CASE 1. A Westfield patient admitted December 26, 1912. April 20, 1914, left ventricular band injected and swollen, also left arytenoid. May 3 left ventricular band much more swollen than any other part of the larynx. Slight pain and huskiness. Right lung involved throughout: one-half of left; general condition good. I made four applications of galvano-cautery by the indirect method at about three weeks intervals. Result—on September 29, throat feels better, voice clearer, swelling less marked, general condition improved.

CASE 2. A Rutland case; man, age 42; pulmonary disease quiescent. Papillary growth on the posterior end of left vocal cord which was treated for several weeks with no benefit; then galvano-cautery was applied; after three applications the cord cleared up but a similar growth appeared on the right cord at point of contact during pronation; same treatment with like results; up to the present time the growths have not recurred and except for a slight roughening the cords appear normal.

I think that this treatment is worthy of wider application. Unfortunately, as yet, we have not been able to get a suitable apparatus for galvano-cautery adapted to the form of electricity in use at the sanatoria and both these patients came to my office for treatment. When we do get it we should have a fuller experience to report.

RÔLE OF THE TONSILS.

The rôle of the tonsils in the infection of tuberculosis is an interesting subject which we have tried to study from a clinical side, namely in examinations of patients to note the presence of tonsils, also the frequency of any apparent disease in them or the history of past trouble. I have also studied this question carefully in the tuberculosis clinic at the Worcester City Hospital and in private practice. We feel that the tonsils are not the definite factors in the infection of tuberculosis that they are by some thought to be. As at Westfield there is a group of children, I asked Dr. Chadwick to make a statement on this subject and the following is a copy of his letter.

"I have had the children's records looked up and some of those who have been discharged; altogether 131 patients under 16 years of age.

We find that 87 of this number show no abnormal condition of the throat; 21 have large tonsils, 23 slightly or moderately enlarged tonsils. Six of this number I operated on and removed the tonsils and adenoids. The condition in the others did not call for operation because they had no symptoms of obstructed breathing.

In our children's ward at the present time there are 69 children. Of this number 11 had but one tonsil slightly enlarged or moderately so. It was noteworthy in 10 of the 11 that the right tonsil was the one which showed enlargement. In 6 both were slightly enlarged, 6 both moderately enlarged and 10 both large.

Although I have no statistics as to the percentage of large tonsils among the group of children such as we find in the public schools, my opinion is that the percentage of large tonsils would be fully as large as I found in this sanatorium group.

There seems to be no relationship between the cases with but one enlarged tonsil and the diseased lung. Pulmonary disease is not more frequently found on the corresponding side. In fact most of these children under 12 years show bronchial gland infection as shown by consolidation of the area between the scapulae.

I agree with you in the statement which you quote, namely,—we are of the opinion that the rôle of the tonsils in the infection of tuberculosis has been very much overestimated."

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY PAUL THORNDIKE, M.D., BOSTON.

KIDNEY AND URETER.

Infections. SWEET and STEWART. (*Surgery, Gynecology and Obstetrics*, April, 1914). The authors believe there is an extensive network of lymphatics connecting those of the bladder and those of the kidney, and that ascending infections travel through this system and not through the blood stream or through the ureteral canal.

BARBER and DRAPER. (*Journal of the American Medical Association*, January 16, 1915.) This paper represents a study of the relation which impaired ureteric function bears to renal infections. The conclusion reached is: "The integrity of the factor of safety which protects the kidneys from hydropic degeneration appears to depend directly on the unimpaired prostatic valve of the ureter, indirectly on the integrity of the ureterovesical valve, and most interestingly on the relationship between these physiologic and anatomic barriers."

COLE. (*Journal of the American Medical Association*, January 23, 1915.) Cole experi-

mented on the effect of the colon bacillus on the kidney and concluded: 1, that a non-traumatized kidney, in the absence of ureteral obstruction, will overcome the bacterial invasion; 2, that the blood stream is the means of extension of these infections from renal pelvis to cortex, and vice versa, and probably, also, from periureteral tissues to the renal parenchyma; 3, that the pathological changes are due to a direct toxic action, soluble toxins being carried also to the opposite kidney.

HARTUNG. (*Berliner Klinische Wochenschrift*, April 20, 1914.) This paper reports sixty experiments in which a one-sided, artificial hydronephrosis is reduced to the effects of various infections studied by comparing the two sides. This work again emphasizes the great rôle hydronephrosis plays as a cause of renal infections.

Calculus; Calculous Anuria. DAVIS. (*Surgery, Gynecology and Obstetrics*, June 6, 1914.) This article is interesting and important because of the writer's statement regarding reflex anuria. He says that the possibility of its existence cannot be denied, but that convincing proof is lacking and that the few cases reported of a reflex inhibition of an unobstructed, but more or less diseased, kidney as the result of calculus obstruction of its fellow are better explained as the functional failure of an overloaded, unsound organ.

Collargol Injections. Numerous papers have been printed during the year dealing with the dangers connected with injecting collargol into the renal pelvis.

WOSSIDLO. (*Archives für Klinische Chirurgie*, Vol. ciii, No. 1.) EISENDRATH. (*Journal of the American Medical Association*, May 2, 1914.) KEYES and MOHAN. (*Journal of Medical Sciences*, Vol. cxlix, No. 1.) The danger seems to be universally recognized and extreme caution advised. Doubtless the near future will produce a technic which can be used with greater freedom and less anxiety to the operator.

YOUNG. (BOSTON MEDICAL AND SURGICAL JOURNAL, April 15, 1915.) In this paper, which has just appeared, Young reports the result of three months' work at the Massachusetts General Hospital with an emulsion of argentide. The summary of his paper states that "collargol is an absorbable kidney poison when used in the renal pelvis." The emulsion of argentide as described here is a clean, non-absorbable, opaque fluid which can be used with minimum danger to the patient and maximum satisfaction to the surgeon.

Tuberculosis. HARBITZ (*Norsk Magazin for Lægevidenskab*, November, Vol. lxxiv, No. 11) reports findings of an old encapsulated, tuberculous process in twelve cadavers at autopsy. He says, "The process had evidently run its course and become encapsulated spontaneously with what amounted to a clinical cure," but, on the other hand,

WOOLSEY (*American Journal of Surgery*, Vol. 28, 1914) insisted upon the propriety of the well recognized present-day custom of early operation, and feels, with most surgeons in this part of the world, that climatic treatment is a waste of time and an unnecessary risk.

BUERGER (*Interstate Medical Journal*, Vol. xxi, No. 11) reports in detail a most unusual case of primary tuberculosis of the renal pelvis and asserts the possibility that in chronic renal tuberculosis bacilli may be filtered from the blood to the renal tubules and from these in turn to the surface of the papillae or calyx recess, where they form a lesion; the anatomical disposition of those parts making for stagnation and poor drainage.

Blood Cyst. O. WULFF. (*Hospitalidene*, Copenhagen, Dec. 9, Vol. lviii, No. 49.) This paper chronicles two unusual cases of symptomless but persistent hematuria in young men in which nephrectomy showed in each case a single benign cyst filled with blood. The cysts were both in the upper pole of the kidney, and the writer says there are only fourteen such recorded cases and that most of these were in children.

Kidney Transplantation. ZAALJER (*Beitrag zur Klinischen Chirurgie*, Tübingen, Vol. xciii, No. 2) details possibly the only case where a kidney was transplanted in a dog from its normal site to the groin and was found adequately functioning and of normal size and consistency six years later. The article is illustrated and the technic is carefully explained.

BLADDER.

Cystectomy. It has long been recognized that operations for malignant disease of the bladder wall have been ineffective and often worse than useless. The point of view that holds such cases should be let alone or else treated by operations of a very radical nature is being more and more insisted upon.

CHUTE (*Journal of the American Medical Association*, December 26, 1914), and SQUIER (*Journal of the American Medical Association*) both advocate more radical operating, and the latter presents a carefully detailed technic for the operation which he calls sub-total cystectomy.

Iodine Fumes in the Treatment of Tuberculous Cystitis. Mention has already been made in previous reports of this method of treating tuberculosis in the bladder, and now NORMAND (*Journal d'Urologie*, Paris, March, 1915, Vol. No. 3) reports a considerable personal experience. He claims satisfactory results, describes the technic, discusses frequency of treatments and says his method is indicated in all cases, both primary and secondary, except during acute exacerbations.

Myiasis. KING. (*Journal American Medical Association*, December 26, 1914.) Larvae of many flies have been found in man, a common one being the *fannia scalaris* or latrine fly. The

literature of the subject is limited and therefore King's case is of interest and value.

PROSTATE.

Since the operation of prostatectomy has become so universally used, much is being added to our knowledge of prostatic cancer, and during the last year a number of notable papers have appeared dealing with this subject.

FREYER (*Archivus Internationalis de Chirurgie*, Ghent, Vol. vi, No. 4; paper written in English) finds that 134, 10% of 1276 cases of enlargement in his own private practice, were cancerous. The difficulty of diagnosis is dwelt upon. Hematuria, he says, is a rare symptom, occurring only in advanced stages, and profuse bleeding points usually to simple adenomatous enlargement rather than to cancer. He makes it clear that cancer may develop in a prostate previously the seat of adenomatous enlargement, and he reports eight cases where such cancerous development occurred and was confined within the limits of the prostatic capsule at the time of operation.

MCGRATH (*Journal of the American Medical Association*, Sept. 19, 1914), in a paper from the Mayo clinic, compares the epithelial changes in prostatic cancer with those of mammary carcinoma, asserts its frequency after fifty years of age, names the posterior lobe as its usual site, and states that it usually occurs at first as a small nodule of slow growth and therefore that "careful investigation of the posterior lobe, gross serial sections of the specimen with microscopic examination of doubtful areas, are essential for diagnosis in the majority of cases."

YOUNG (*American Journal of Urologie*, June, 1914) reports a series of cases, calls attention to the fact that a study of two hundred cases, most of them advanced, shows that ulceration of both vesical and rectal mucosa is uncommon, and intravesical tumor growth equally so. He says two layers of Denonvillier's fascia are largely responsible for confining the cancer to the prostate and thus protecting the rectum. Young's paper includes a description of technic for a radical operation and reports six of his own cases where such an operation was performed.

Syphilis. WRIGHT (*Transactions of Chicago Urological Association*, November, 1912) reports a case of syphilis of the prostate, which is mentioned here because of its rarity.

Colliculectomy. RYTINA (*Journal of the American Medical Association*, Jan. 2, 1915) describes an instrument and an operation for the radical removal of the verumontanum, a procedure which he thinks "less liable to untoward complications and sequelae than strong applications of silver nitrate thermocautery."

TESTIS.

Tuberculosis. BARNEY. (*Journal of the American Medical Association*, Dec. 26, 1914) Bar

ney's rather statistical paper is of value because of the material back of it. He points out the fact that in genito-urinary tuberculosis (a useless term) it is the genital tract which is usually first affected, and that the process is secondary to similar disease in other parts of the body in more than half the cases. He quotes one hundred epididymectomies, an operation which he highly advocates, and says that in no case has the necessity arisen for a subsequent orchidectomy,—a most unusual experience.

SIMMON. (*Beiträge zur Klinik der Tuberculose*, Würtzburg, Vol. xxxiii, No. 1.) This paper is interesting in connection with the one above, as substantiating more or less Barney's statement that the genital tract is usually the first to become involved. The writer quotes findings in 105 cadavers in which the genital system was alone involved, and in 95 other cases the tuberculous process had affected the kidney or the bladder as well. In the genital tract he believes the prostate to be the primary seat in about half of all cases; the seminal vesicle and testis about 25% each.

Tumor. HINMAN. (*Journal of the American Medical Association*, Dec. 5, 1914.) This really valuable paper, which describes new and radical technical procedure, also points out that in almost every case of cancer the earliest metastasis occurs first in a limited area of lymph nodes in the lumbar region, between the bifurcation of the aorta and vena cava below, and the renal pedicle above. He also believes that the pathological division of tumors of the testis into embryonal carcinoma and mixed cell types is an arbitrary one, as both are teratomas, and yet such a division is of value clinically, as it seems to be a fact that the former class is less likely to metastasize, although of more rapid growth, while the latter, although of slower growth, has a smaller percentage of cures from operation.

Sterility. WHEELER (*British Medical Journal*, Feb. 7, 1914) describes an ingenious anastomosis operation for the vas deferens in which the divided ends are passed over the eye and point of a fine needle until they meet. Sutures are then inserted, and finally the needle is pushed through the wall of the vas at a distance from the point of union.

LESPINASSE (*Journal of the American Medical Association*, Nov. 28, 1914) describes an ingenious operation for male sterility in those cases, more than half of all of them where the vas is obstructed above the internal ring, and behind where ordinary anastomosis is impossible. The operation aims at the production of an artificial sac, communicated with the epididymitis and serving as a receptacle and storehouse for the sperm discharged into it. This sac can be tapped whenever sperm is desired for impregnating purposes. At the time of publication this method had never been tried on men, but the writer had operated seventy-one times on dogs. This seems

a somewhat fantastic article, but is really a clever and an interesting idea.

GONOCOCCUS.

CRABTREE. (*Journal of Infectious Diseases*, Sept. 19, 1914). This paper is written to combat Warden's contention, which was briefly that the staphylococcus albus, under certain conditions, loses its power to hold Gram's stain, and that intracellular diplococci in the pus of gonorrhea are probably not gonococci at all but are the Gram negative staphylococci in diplococcal form. Crabtree concludes that the staphylococcus albus has no stage of growth in which it is a gram negative organism and, therefore, that Warden is wrong.

TESTS FOR RENAL FUNCTION.

In 1909 Rowntree and Geraghty advocated the use of phenolsulphonephthalein as a test for renal function. They believed that many of the difficulties which pertained to other similar tests had been overcome, and their contention was sustained by the publication, during the next few years, of a large number of articles all over the world. Now comes the report of many observations in this very significant and valuable paper from the Mayo clinic.

BRAASCH and THOMAS (*Journal of the American Medical Association*, Jan. 9, 1915) Their conclusion so entirely coincides with the writer's point of view in such matters that he cannot refrain from printing it verbatim. "We should like to emphasize that it is not our purpose to belittle Geraghty and Rowntree in their thoroughly scientific efforts to establish a chemical estimate of renal function. The phenolsulphonephthalein test, because of the ease of application and rapidity of secretion, remains as probably the best functional test at our command. Nor is it our purpose to detract from the value of a careful examination of the character of ureteral secretion in surgical conditions of the upper urinary tract. It is our contention, however, that the fundamental surgical principles and clinical data should determine whether or not an operation is indicated; and that renal functional tests are of practical value largely as an aid to differential diagnosis and only to a limited degree as a prognostic aid."

MILLER and CABOT. (*Archives of Internal Medicine*, March, 1915.) The writers have used the phenol sulphonephthalein test as a means of studying the effect of anesthesia and operation upon kidney function in 422 cases at the Massachusetts General Hospital. Some of their conclusions follow: "The output of phenolsulphonephthalein by the kidneys grows progressively less with advancing years. There is a normal daily variation in its excretion influenced by many factors. After operations under ether there is a decreased output, the decrease being greater in laparotomies than in the general average, and considerably greater in cancer cases.

The sooner after operation the test is done the greater the decrease, the output returning to about normal in from twenty-four to forty-eight hours. The more ether that is used and the longer the operation, the greater the decrease in phenolsulphonephthalein excretion. Some cases show no decrease, others great decrease or almost total inhibition of excretion without discoverable cause. Shock causes great decrease, as does also any condition of much impaired vitality. There is no definite relation between decreased drug excretion and the occurrence of albuminuria after operation."

Creatinin Test. In this day, when many tests for renal function are receiving attention and interest from the profession, this one of NEUBAUER (*Münchener Medizinische Wochenschrift*, April 21, 1914), is not without interest. He states that if 1.5 grams of creatinin are dissolved in 100 or 150 c.c. of sweetened water and are given to patients, those with normal kidneys will eliminate from 60 to 90% of the creatinin in the next six hours, while those with diseased kidneys will eliminate but 20% or less during that time, the remainder of it taking days to be disposed of. The test does not seem to be one of those destined for general usefulness, but is of interest and may be of importance in many cases that are of a non-surgical character.

Complement Fixation Test. McNEIL (*New York Medical Journal*, August 22, 1914). Three years ago the writer of this paper presented certain conclusions regarding this test, as follows: "A positive reaction denotes the presence of recent activity in the body of a focus of living gonococci. A negative reaction does not exclude gonococcus infection but is of considerable importance. A strong positive reaction is not to be expected earlier than the fourth week, and then only in very acute cases with some complication, and the reaction does not entirely disappear until seven or eight weeks after cure. A positive reaction is not obtained if the disease is limited to the anterior urethra."

This present paper is of value because it is based upon 5381 examinations made at the serological laboratory of the New York Health Department. It does not, however, materially alter the conclusions instanced above, which the writer published in the former paper.

Hexamethylenamin. The almost universal use of this drug as a urinary antiseptic has brought forth during the last year numbers of articles concerning its real value, and the following paper is typical of many others.

L. H. LEVY AND A. STRAUSS. (*Archives of Internal Medicine*, Chicago, November, 1914.) The conclusions reached are, that to be of value formaldehyd must be liberated in strengths varying from 1 to 15,000 to 1 to 5000, depending upon the organism to be inhibited; or from 1 to 5000 to 1 to 1000 as a bacterial drug; in this latter case, also, depending upon the organism present. High acidity is necessary in all cases

excepting typhoids, and this high acidity, combined with the formaldehyd present may produce injury to kidney tissue.

Grosz (*Wiener Klinische Wochenschrift*, May 28, 1914) advances the following technique as a test for the presence of hexamethylenetetramine in the urine: "Add to the urine enough 10% acetic or hydrochloric acid to five-fourths or four-thirds the total; then add, a drop at a time, a saturated aqueous solution of mercuric chloride. A fine-grained sediment is positive."

Reports of Societies.

THE SUFFOLK DISTRICT MEDICAL SOCIETY.

A MEETING OF THE SURGICAL SECTION, FOR THE DISCUSSION OF HOSPITAL EFFICIENCY, WAS HELD AT THE BOSTON MEDICAL LIBRARY, WEDNESDAY, JANUARY 6, 1915.

The following papers were read:

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF AN EFFICIENCY EXPERT.¹

By MR. FRANK B. GILBRETH, Providence, R. I.

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF A HOSPITAL SURGEON.²

By DR. ROBERT L. DICKINSON, Brooklyn, N. Y.

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF A HOSPITAL SUPERINTENDENT.

By DR. HERBERT B. HOWARD.

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF A HOSPITAL TRUSTEE.³

By DR. WALTER WESSELHOEFT, Cambridge, Mass.

HOSPITAL EFFICIENCY FROM THE STANDPOINT OF A PUBLIC SERVANT.

By HON. JAMES M. CURLEY, Mayor of Boston.

DISCUSSION.

DR. JOEL E. GOLDSWORTHY: In the organization of most of our hospitals the trustees are the legal owners of the property or are the agents of the actual owners. It is their duty to see that the property for which they are responsible is developed in the best possible manner and that it is made to pay the largest possible dividends in the form of medical service. As a part of their duty a staff is selected and appointed for the particular purpose of attending to the medical care of those to whom the service is offered. As a still further part of their duty a superintendent is appointed to see that the mechanical part of the maintenance of the institution is properly cared for. A superintendent of nurses is appointed to see that the nursing is prop-

¹ See JOURNAL, page 774.

² See JOURNAL, page 775.

³ See JOURNAL, page 778.

erly developed. A social service worker should be appointed to act for the trustees to see that those being received into the wards are suitable cases and also to see that the hospital work is checked up in relation to efficiency by keeping track of the patients after they leave the hospital. These and other appointments should be made for the purpose of developing the work upon the broadest lines and in the most efficient manner that is possible.

All of these appointments should be made by the trustees and the appointees should be directly responsible to them. With the staff they are not only directly responsible to the trustees, but the two bodies should meet together from time to time to discuss methods of development of the work and for interchange of opinions. The lack of opportunities for meeting between these two bodies is one of the greatest reasons for the inefficiency of the service in some of our institutions today.

Since the final authority and responsibility rests with the trustees, the work of the staff should be carefully scrutinized to be sure that the work is being properly performed. It is not an uncommon thing to find occupying staff positions in our institutions today, busy men, too much absorbed in private or other work to attend properly to the work of the hospital. A man's reputation should not be the thing that determines his selection or his continuance upon the staff, but the character of his work alone should be the test. If he has not time to organize or perform the work, he is a hindrance to the hospital, no matter how great his reputation may be. The "output" under some younger or less known man would be vastly greater. It is the duty of the trustees themselves, or through unprejudiced experts, to pass upon the character and efficiency of this work. In considering the staff the laboratory heads are, of course, included, the same scrutiny being given to the work performed there as to the work in the wards.

The superintendent is appointed by the trustees and should naturally be expected to develop the mechanical part of hospital life in the best possible manner, and the same high standard of efficiency should be insisted upon from him as from the staff. The staff should in no way be responsible to the superintendent, since their work is entirely different and each should be held responsible to the trustees, and not each to the other.

The superintendent of nurses should also report directly to the trustees and not through the superintendent of the hospital, since their functions are naturally different.

The social worker, if used right, is one of the most valued aids to the trustees in determining the character of the work performed. The result of the work done should be known not only when the patient leaves the hospital, but at intervals extending over many months, the ultimate result being that which interests the patient most and should be of the greatest interest to the trustees as well as to the staff. The most practical method of keeping up this part of the work is the system of "follow-up" cards such as have been urged so strongly by Dr. Codman.

Each of these departments is part of the hospital machine. Each is important. Each should know what the other is doing and for this purpose meetings should be held, at which each department is represented, for opportunity for free exchange of ideas as they apply to the work of the institution. It is team work, and as in other teams the star

player is of little use in the game unless he will subordinate his desire to the general good. No one department is better than another. Each is part of the work, and the final responsibility rests with the trustees.

This body should be so organized that it can not only know what is being done, but so that it can give proper consideration or support to whatever requests are made. Its own efficiency depends upon the organization, and since it is not to be expected that any one individual can comprehend all of the many details of hospital life and service, it at once means that the whole body should be divided into committees. Those with proper training should look after the finances and see that the purely business part of the work is satisfactory. Those having medical knowledge should be responsible for the medical oversight of the work, with any other subdivisions as are needed, but with the entire board meeting at sufficiently frequent intervals for all to be in a general way familiar with the work as a whole. So much is involved in this that great care should be given to the selection of the members of such boards so that the broadest kind of medical and business direction can be given by the body that is held ultimately responsible.

Book Reviews.

Case Histories in Diseases of Women, Including Abnormalities of Pregnancy, Labor and Puerperium. A Clinical Study of Pathological Conditions Characteristic of the Five Periods of Woman's Life. By CHARLES M. GREEN, A.B., M.D., Professor of Obstetrics and Gynecology in Harvard University; Senior Surgeon for Diseases of Women, Boston City Hospital; Visiting Physician, Boston Lying-in Hospital. Boston: W. M. Leonard. 1915.

Dr. Green's book presents the collected experience of a lifetime spent in the teaching and practice of gynecology and obstetrics. It is his well-known class-room and clinical teaching transferred to print, and constituting an attractive volume of 477 pages.

It is particularly fitting that Dr. Green should have added this book to the Case History series, for he was the first to use the case history method in teaching at the Harvard Medical School, his first attempt along this line dating back to 1891, when by special permission of the faculty he first instituted a voluntary exercise in obstetrics which subsequently became a required part of the curriculum.

The book is divided into five sections: Infancy and Childhood, Puberty and Adolescence, Maturity, the Climacteric, and Anility. At the commencement of each section is given a brief synopsis of the field covered, which is followed by the illustrative cases. In each division of

the book, the author has followed a logical arrangement by pathological processes rather than by organs. He takes up successively functional disturbances, malformations and displacements, infections, traumata, and neoplasms. This is a great improvement over the ordinary more or less haphazard system of dividing the subject of gynaecology into diseases of the separate organs, since in the pelvis the same pathological process almost necessarily will involve more than one, and frequently all of the pelvic organs.

The cases are presented with simplicity and clearness just as they come to the physician in the hospital clinic or in private practice. The author also goes into many cases drawn from his wide experience in private practice in which delicate moral and ethical questions have arisen, which are not discussed in the ordinary text-book of gynaecology, and are seldom or never encountered in the hospital clinic. These are to be found especially in the portion of the book dealing with adolescence and early married life.

In the section on maturity a series of case histories illustrating the common obstetric difficulties and the more frequent complications of the puerperium is inserted, lending completeness to the work. A number of temperature charts representing pathological puerperia give additional clearness to the text. Dr. Green gives the reader perhaps a little too optimistic view of the results of the treatment of eclampsia and also of the treatment of sterility.

A few excellent illustrations from photographs are added to the text, although the book is not intended to be freely illustrated. There is a very complete index, an important part of any book, and one which is too often slighted.

Altogether the book is one which every practitioner who does obstetrics, whether as a part of general work or as a specialty, should use both for reading up and for reference. He will find situations parallel to those which he himself has to meet and the best way of handling them described in a practical manner. As a text-book for class-room use, the work, in common with the other more recent volumes of the Case History series, would be of greater value in teaching if the cases were presented purely as problems and the answers withheld for discussion by the student and instructor. In the attempt to put out books useful for the practitioner as well as the student, the tendency has been to lose sight of the primary use of this form of text-book.

The Commoner Diseases. Their Causes and Effects. By DR. LEONHARD JORES. Authorized translation by WILLIAM H. WOGLON, M.D. Philadelphia and London: J. B. Lippincott Company.

Jores is professor of pathology and pathological anatomy at Marburg. His book represents a series of 34 lectures in pathology. There are

some 250 illustrations in the text, mostly photographs from pathological specimens. The author does not pretend to cover every branch of morbid anatomy. Inasmuch as he rather strictly adheres to his plan of devoting a chapter or lecture to a single subject or an allied group of subjects, the space allotted to various subjects is often disproportionate, not only to the importance of the subject, but also to the material which must be reviewed. Contrary to what might possibly be assumed from the title, the book is not clinical and does not concern itself with diagnosis or treatment. It does represent, however, a careful, sound, even if rather cursory, discussion of the pathological findings in the commoner diseases.

Modern Medicine. Its Theory and Practice. By SIR WILLIAM OSLER, Bart, M.D., F.R.S.; and THOMAS MCCRAE, M.D. In five octavo volumes of about 1000 pages each. Volume IV. Diseases of the Circulatory System; Diseases of the Blood; Diseases of the Lymphatic System; Diseases of the Ductless Glands; Vasomotor and Trophic Disorders. Philadelphia and New York: Lea and Febiger. 1915.

The fourth volume of this standard text-book by distinguished authors now appears in its second edition. Dr. Osler himself contributes the section on "Vasomotor and Trophic Disorders" and also the chapters on "Acute Endocarditis," "Valvular Heart Disease," "Aneurysm," and "Diseases of the Arteries." Dr. Maude E. Abbott contributes a very remarkable chapter on "Congenital Cardiac Diseases," that is almost a monograph in itself. This portion has been very largely rewritten. Dr. Thomas Lewis appears in this second edition for the first time as a contributor. His chapter on "The Rate and Mechanism of the Heart Beat" is a clear short exposition of that subject. All the chapters are excellent and show the effect of careful revision.

Aids to Dental Anatomy and Physiology. By ARTHUR S. UNDERWOOD, M.R.C.S., L.D.S. New York: William Wood and Company

This manual in the Students' Aids Series aims to form an introduction to the study of dental histology. This third edition has been modified in accordance with the important advances of recent years, notably in the subjects of calcification and the innervation of dentine. This subject of calcification is especially treated in an appendix by Mr. J. Howard Mummery. The chapter on microscopy has been omitted. The book should continue a useful guide to dental students.

ROBERT B. OSGOOD, M.D., *Boston, Secretary.*

ERNEST GREGORY, *Manager.* W. M. LEONARD, *Consulting Manager.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

HOSPITAL EFFICIENCY.

IN the spring of 1914, the Philadelphia County Medical Society appointed a committee to consider the ways and means by which the efficiency of hospitals in Philadelphia might be increased. After an extensive study of the situation this committee presented its results in a series of three reports, with an introduction on the principles of hospital efficiency by the secretary of this committee. These results and recommendations were editorially reviewed in the *Journal of the American Medical Association* for February 6, 1915.

On January 6, 1915, a meeting for the discussion of hospital efficiency was held at the Boston Medical Library under the auspices of the surgical section of the Suffolk District Medical Society, and in the issue of the JOURNAL for January 21 we commented editorially on this meeting and on the principles of hospital efficiency

and the methods by which their attainment should be sought. In the present issue of the JOURNAL we take pleasure in publishing the principal papers presented at this meeting and an abstract of their discussion.

The astonishing results which have followed the efficiency crusade wherever the attention of the experts has been focused on any special problem can but encourage us to look for marked improvement in hospital management now that the business of the "happiness factory," as one of the writers on hospital efficiency, whose article appears in this issue of the JOURNAL, has termed the hospital, is being critically studied.

With the general principle of survey work in the hospital, we are in hearty accord. There can be no question but that the wage scale and living conditions of employees in many institutions demand quite as acutely as factories very careful scrutiny. A low cost per capita per day resulting from sweat shop conditions and poor food means, of course, inefficiency, though it has been at times commended.

The patients and the public should receive in every way the maximum in service from the available supply of scientific knowledge and funds. Besides the immediate care of patients, the hospital has a responsibility to the community in establishing standards of hygiene, and the information contained in the records should constitute valuable data bearing on many of the large public questions.

In so far as the purely business part of the hospital is concerned, the checks which have been found to be valuable to commercial ventures, such as hotels and factories, should be instituted. The general introduction of a comprehensive system of institution book-keeping, a problem which has interested the progressive hospital superintendent for years, would be of great value, and it is evident that a closer coöperation between institutions in the matter of the purchasing of supplies must needs lead to a material saving. To this end no studies in efficiency can be carried out for a more worthy purpose or with greater hopes of producing results.

That the attending staffs in many institutions fail to render the maximum service in their care of the sick and that many boards of trustees are delinquent in the seriousness with which they assume their responsibilities cannot be denied. A certain degree of standardization of methods and routine in the care of patients should improve conditions. Careful follow-up systems,

which will show the actual results of treatment, are checks which the trustees and the public must insist upon in order that the character of the work done in the hospital and by the individual attendant may be justly judged.

On the other hand, it is to be remembered that too great systematization tends to produce unthinking routine. The painstaking study of the individual case is what has advanced medical knowledge, rather than a compilation of book-keeping results obtained from the analysis of a large series of cases. Accurate as modern science has made the practice of medicine, it is still, to a degree, an art. The ills from which mankind suffer do not occur with sufficient precision to make the establishment of many of the efficiency tests applicable. It should not be forgotten that the patient is an individual, and that the physician or surgeon in charge is an individual. To minimize this fact and consider the treatment of the patient as simply a piece-work problem and the attendant in the light of a skilled workman would be deplorable.

With the point of view that the shortcomings of the hospital should be placed mainly at the door of the trustees we are not at all in sympathy. By and large, the men who serve as trustees of hospitals are men of integrity and high ideals. They are vitally interested in everything which increases efficiency. They may be misguided in their interpretation of what constitutes efficiency, but it is our opinion that they need guidance rather than condemnation. The whole tendency of today is to break down the traditional barriers between the purely administrative directors of the hospital and the medical staffs. This is evidenced from the increasing number of hospital boards who request a number of members of the attending staffs to meet with the trustees. If this spirit of coöperation is fostered and if, with the combined wisdom of the lay and professional boards, the three essentials of hospitals—"to care for the sick, to assist in the education of students, and to contribute to the advancement of medical knowledge"—are borne in mind, properly directed efficiency studies will play an important part in helping to formulate the broader ideals of hospital service.

Perhaps after all the conclusion of the whole matter is best summarized and stated by the following resolutions adopted as a result of the Boston meeting on hospital efficiency:—

"That the committee of supervision, acting for the Suffolk District Medical Society, ap-

proves of the movement to secure greater efficiency in our hospitals.

"That it believes the adoption of the principles of the 'end result system' in hospitals would be conducive to greater efficiency of those institutions.

"That the president of the society is authorized to appoint a committee which shall inquire into the practical application of this system and shall later make a report and recommendations to the society."

RECENT IDEAS ON VENTILATION.

UNDER the title "Standards of Ventilation in the Light of Recent Research," Professor C.-E. A. Winslow describes the results of the investigations of the New York State Commission on Ventilation during the past year.¹ He points out that the former *bête noir* of sanitarians, carbon dioxide, is no longer to be regarded as a poison; that insufficient ventilation does not mean a lack of oxygen for breathing purposes and an excess of carbon dioxide, as taught only a short time ago. In other words, it is not the chemical composition of the air we breathe that is the important factor, but physical conditions—the temperature, the humidity and the air movement.

Experiments were conducted by the New York commission in two rooms of the College of the City of New York, equipped so that atmospheric conditions in one room could be very closely controlled by apparatus situated in the other. In the observation room over one hundred different subjects in groups of four were exposed for periods of from three and a half to eight hours a day for from one to eight weeks in each series of experiments, to known conditions of temperature and humidity and atmospheric vitiation, and their physiological and psychological reactions, and their mental and physical efficiency were observed and measured by the most exhaustive methods.

Stagnant breathed air, contaminated by a group of subjects so as to contain on an average from 20 to 60 parts of carbon dioxide per 10,000, proved to be entirely negative so far as the elaborate physiological, psychological and efficiency tests were concerned. Quite extreme conditions of heat and humidity (86° with 80% relative humidity) had no measurable effect on the rate of respiration, on dead space in the

lungs, on acidosis of the blood, on the respiratory quotient, on the rate of digestion and rate of heat production (both measured by oxygen consumption), on protein metabolism (measured by determinations of creatinine in the urine), or on skin sensitivity. On the other hand, the working of the circulatory and heat regulating mechanism of the body was markedly influenced by even a slight increase in room temperature, as, for example, from 68° to 75°, with 50% relative humidity in both cases. A high room temperature (86°) produced an average rectal temperature in all subjects of 37.41° C., whereas the rectal temperature averaged 36.73° C. when the room was at 68°. The systolic blood pressure averaged 112 when the room was at 86° and it averaged 116 with the room at both 75° and 68°. The average amount of physical work accomplished during the day was rated as 137 with the room temperature 68°, and 100 with a temperature of 86°. This was in summer. In the fall the figures were 114 and 100 for the same room temperature respectively.

Interesting improvements in the engineering of modern ventilation are explained by Mr. D. D. Kimball, another member of the New York State Commission on Ventilation.² Ten years ago, he tells us, the mechanical efficiency of the ventilating fan customarily used was about 45%. Now, the best type of fan (the multi-blade) has an efficiency of 65%, thus effecting a saving of more than 30% of the power expenditure for ventilation. He describes air washing and the recirculation of the air used for ventilation. The air washer consists of a sheet metal chamber in which air is passed through a heavy mist and then through eliminator plates by which the air is so deflected that the contained moisture is removed. According to the researches of Mr. M. C. Whipple, of Harvard University, the air washer removes from 64% to 7% of dust, certain dusts not being removed to any appreciable extent. Such air washers are used in many industries, such as candy and macaroni making, the preparation of photographic films and in textile manufacturing.

The conclusion reached by the New York commission was that there seemed to be no appreciable difference between washed recirculated air and outdoor air similarly treated so far as bodily comfort is concerned. Naturally the proportion of carbon dioxide is greater when using the recirculated air, but no significance was attached to this fact.

Mr. Whipple thought: "That recirculation provided a plentiful supply of air with no apparent sacrifice of wholesome properties, and that it is a safer source of supply than outside unwashed air." Odors were not noticeable to those occupying the room during the use of recirculated and washed air, although sometimes barely noticeable to one entering from out-of-doors. Recirculation manifestly saves a large amount of heat and, in the opinion of Mr. Kimball, its use may prove to be a great step in advance in the field of mechanical ventilation.

The desiderata in ventilation would seem to be, regulation of the room temperature, generally elevated by the numerous bodies of human beings at 98.4°, regulation of the humidity, also raised by the respiration and perspiration of the people in the room, and washing the air and keeping it constantly in motion.

THE VETO OF THE CLEAN MILK BILL.

IN various previous issues of the JOURNAL we have from time to time commented editorially on the so-called Labor Clean Milk Bill in various stages of its legislative progress, and in last week's issue we published the circular letter of the president of the Massachusetts Medical Society urging the signature of the bill by the governor. Unfortunately the governor's unexpected and regrettable veto of this bill, which was returned to the Senate on May 20, puts a check at the last stage to this desirable piece of public health legislation, unless sufficient strength can be mustered by its advocates in the General Court to pass the measure over the veto.

The subject of clean milk legislation has been agitated before the public for over five years, and previously the Ellis milk bill, the predecessor of the present measure, after being successfully passed by the legislature, has been killed by the gubernatorial veto. Apparently the decision to veto the present measure was, in part at least, influenced by a meeting held in Worcester on May 19, at which five hundred milk producers, representing thirty-four cities and towns of Worcester county, unanimously adopted a resolution of protest requesting the governor to veto the bill. In his veto message, the text of which is printed in another column, the governor states that there is already suffi-

cient law on the statute books to protect milk consumers; that the proposed bill is so stringent that it would only impose additional hardship on Massachusetts farmers and milk producers without giving consumers enough additional protection to justify the legislation. The message lays especial further stress on Chapter 744 of the acts of 1914, relative to the production and sale of milk, which, it is alleged, furnishes all the protection necessary:—

“Chapter 744, acts 1914, makes it unlawful for any producer of milk, or dealer, to sell or deliver for sale in any city or town in the commonwealth any milk produced, or dealt in by him, without first obtaining from the board of health of such city or town a permit authorizing such sale or delivery. Provision is made in the act for examinations of the place in which such milk is produced and the boards of health are further authorized to make such reasonable conditions in the permit as the board may think suitable for protecting the public health.”

Naturally these reasons will not appear satisfactory or adequate to members of the medical profession and to others who have coincided with the JOURNAL in its editorial opinion, strongly advocating the passage of the clean milk bill. Apparently this desirable piece of legislation, again nearly at its consummation, has again been defeated by the influence of milk producers who, in the past, have uniformly opposed this and similar legislation. It is still possible, however, that the bill may be enacted into law by a two-thirds legislative vote passing it over the governor's veto. Circular letters, urging this action, have already been sent to all members of the Senate by the Boston Milk and Baby Hygiene Association and the Massachusetts branch of the American Federation of Labor. It is earnestly to be hoped that physicians and all others who have concerned themselves with this measure of public health will again give their support and aid by writing to their senators and representatives, urging the passage of the bill in this definitive manner.

Since the above was in print, the Senate, on May 21, by an almost strictly party vote, sustained the governor's veto.

COMPLIMENTARY DINNER TO DR. THEOBALD SMITH.

THE postponed complimentary subscription dinner to Dr. Theobald Smith, upon the

occasion of his completion of more than twenty years of service to the Harvard Medical School, is to be held at the Harvard Club, Boston, on Wednesday evening, June 2, at 7 p.m. In the issue of the JOURNAL for March 18 we published a brief editorial statement of Dr. Smith's services to his college and to the advancement of medical science, and extended to him the felicitations of the profession and the expression of its cordial good wishes and confidence in his promise of even greater achievement in the new and larger duties to which he goes, in conjunction with the work of the Rockefeller Institute for Medical Research in New York. To these feelings are now added those of grateful congratulation for his happy recovery from the illness which made necessary the postponement of this meeting in his honor. President Lowell is to preside at the dinner and already 150 acceptances have been received, so that a large and successful gathering is assured. It is even more to be desired, however, that as many physicians as possible should take advantage of this opportunity to express the appreciation and realization of the profession of the importance and distinction of Dr. Smith's service to medical science and research, and all who have not already planned to attend this occasion are cordially invited and urged to do so. The subscription (\$5.00) of all those wishing to take part should be sent prior to the dinner to Dr. Marshal Fabyan, 379 Commonwealth Avenue, Boston.

VOLUNTEERS FOR THE HARVARD SURGICAL UNIT.

ATTENTION is called to the notices published on the last page of this issue of the JOURNAL, calling upon physicians and nurses to volunteer for service, in England or in France, on the second Harvard surgical unit, now being organized. The expedition will start from Boston early in June, and is destined for six months' service in Europe, until January 1, 1916, unless the war is sooner ended. The details of this work are stated in the notice. This is a service which calls for volunteers of the highest grade and qualifications, and for the honor of the New England medical and nursing professions it is expected that there will be an abundance of well fitted volunteers.

MEDICAL NOTES.

AMERICAN PROCTOLOGIC SOCIETY.—The seventeenth annual meeting of the American Proctologic Society will be held at San Francisco, California, on June 21 and 22, 1915. The profession is invited to attend all meetings.

BUBONIC PLAGUE IN HAVANA.—Report from Washington, D. C., on May 11 states that two more cases of bubonic plague have been discovered in Havana, making a total of fourteen cases since the beginning of the outbreak six weeks ago. American and local officials are working in conjunction to eradicate the plague.

PREVALENCE OF MENINGITIS, MALARIA, PELLAGRA AND POLIOMYELITIS.—The weekly bulletin of the United States Public Health Service for May 7, 1915, states that during the month of March, 26 cases of cerebrospinal meningitis were reported in New York State. During the same month, in Mississippi there were reported 16 new cases of meningitis, 4596 of malaria, 621 of pellagra and 39 of poliomyelitis.

WASHINGTON UNIVERSITY MEDICAL SCHOOL.—At the recent dedicatory exercises of the new buildings of the Washington University Medical School, St. Louis, a number of honorary degrees were conferred. Among these the degree of Sc.D. was given to Drs. W. T. Porter and O. E. Folin of the Harvard Medical School and to Dr. Theodore Janeway. The degree of LL.D. was conferred, among others, on President Lowell, Dr. Simon Flexner and Dr. W. H. Welch.

SMALLPOX ABOARD THE CHARLESTON.—Report from Seattle, Wash., on May 16 states that the United States cruiser *Charleston* has been quarantined at that port on account of the discovery of two cases of smallpox among recruits aboard.

WATER FILTRATION PLANT AT ST. LOUIS.—On May 15 there was dedicated at St. Louis a new water filtration plant which has recently been completed at the extreme northern end of the city at a cost of \$1,300,000. The daily capacity of this plant is 150,000,000 gallons and, in cases of emergency, 200,000,000 gallons.

"The opening of the filtration plant is the last step deemed necessary for years to assure St. Louis of clear water. The city's water is taken from the muddy Mississippi River, and first is given a chemical treatment that precipitates the solids and foreign matter. The water then passes through a series of settling basins, from which it emerges clear. For years this system was sufficient to assure the city clear water, but as the demands for water grew with the growth of the city, it was noticed that in hot weather or when the river was unusually muddy, the water was drawn through the settling basins so fast that it poured out of the faucets slightly

discolored. The great sand filter then was built. The water now will pass from the settling basins into the filter, and thence into the mains. The filter, it is believed by engineers, will assure the people of St. Louis absolutely clear water."

CARE OF THE FEEBLE-MINDED.—The subject of the care of the feeble-minded was discussed on May 17 at one of the section meetings of the National Conference of Charities and Correction in session at Baltimore. Mr. Amos W. Butler, secretary of the Indiana State Board of Charities, presented a report of an investigation of the number and care of the feeble-minded throughout the United States.

"The most conservative estimate of the number of feeble-minded in this country is one in every 500 of the population. This means 200,000. About one-tenth of this number are receiving proper care. At least two-thirds of the feeble-minded have inherited their feeble-mindedness. The average number of children born in a family is four, whereas in the degenerate families we find 7.3 each. One study of the mentality of truants shows upwards of 80% of them feeble-minded. Many different studies show from 46% to 89% of reformatory inmates to be feeble-minded. If these statements should be taken at only half their value, they still show a condition important enough to need prompt action."

NEW YORK CITY'S HEALTH LAST WEEK.—There were 1472 deaths and a death-rate of 13.23 per one thousand of the population reported during the past week, as compared with 1533 deaths and a rate of 14.32 for the corresponding week in 1914,—a decrease in the absolute number of deaths of 61 and in the rate of 1.09 points, which is equivalent to a relative decrease of 121 deaths.

Scarlet fever, typhoid fever, organic heart diseases, pulmonary tuberculosis, and chronic Bright's disease, all showed a decreased mortality.

Those causes showing an increased mortality were measles, whooping cough, tuberculous diseases (other than pulmonary tuberculosis), diseases of the nervous system and violence.

Viewed from the point of age grouping, there was a considerable increase in the deaths of children under one year of age and of children between one and five years of age, which was more than offset by the decreased mortality at the age groups of 5 years and over.

The death-rate for the first twenty weeks of 1915 was 14.63 per one thousand, as compared with a rate of 15.35 during the corresponding period of 1914, a decrease of .72 of a point.

AN EDUCATIONAL LUNCH ROOM.—The Bureau of Public Health Education of the city of New York has opened an educational lunch room, in which carefully arranged luncheons are provided at low cost with the object of furnishing

wholesome food at cost price and of educating its patrons in food values and nutrition. Appearing on the menu is a statement of the number of calories and grams of protein each article contains.

TUBERCULOSIS IN THE FRENCH ARMY.—Professor L. Landouzy of Paris has published in the *Revue d'Hygiene* an article calling attention to the danger of rapid spread of tuberculosis in the French army, due to the massing of soldiers in restricted areas, such as trenches and during siege operations, where it is impossible to protect the well from such tuberculates as may be in their ranks. In a condition of peace it has been estimated that in eight years the number lost to the army was 36,000, so that the present army may lose not fewer than 30,000 a year from this cause. Dr. Landouzy makes the suggestion that known tuberculates be given posts and stations in the outlying districts apart from the segregations of soldiers in trenches and forts.

GORGAS PRIZE MEDAL.—Referring to the Gorgas prize medal, to be awarded yearly by the Association of the Medical Reserve Corps, U. S. Army, New York State Division, the board of award makes the following announcement:—

The competition is open to medical officers of the Army, officers of the Medical Reserve Corps of the Army, and medical officers of the Organized Militia.

The medal will be awarded for the paper submitted which shows the most important advance in medicine or surgery on a medical or medico-military subject, preference being given to papers on a medico-military subject.

The medal will be awarded only for papers of exceptional value.

The board of award consists of three members of the faculty of the Army Medical School, appointed by the Surgeon-General, U. S. Army.

The papers should be submitted to the Board of Award, Gorgas Prize Medal, by March 31 of each year, and should be addressed to the President of the Board of Award, Gorgas Prize Medal, Army Medical School, Washington, D. C.

The award will be announced at the graduation exercises of the Army Medical School, on May 31 of each year.

EUROPEAN WAR NOTES.—It is reported from Philadelphia that early in June another surgical unit will sail from that city for service in military hospitals of France and England. The leaders of this unit will be Dr. J. William White, Dr. R. Taite McKenzie and Dr. James P. Hutchinson. The unit will be stationed primarily at the American Ambulance Hospital at Paris, and, in addition to the above named, will consist of a number of physicians and nurses. Dr. Hutchinson will be the chief surgeon.

In the issue of the JOURNAL for May 6 we noted a proposition by Sir William Osler, of Oxford, that the Harvard Medical School should send abroad in June, for service in an English government field hospital, either in France or in England, a second surgical unit, to consist of twenty-four surgeons and seventy-five nurses, and to have charge of over one thousand beds. The unit is now in process of organization and will be under the leadership of Drs. Edward H. Nichols, Charles A. Porter and William E. Faulkner of Boston. It is probable that as many as thirty-two, instead of twenty-four, surgeons will compose this unit, which is to undertake a service of six months. In last week's issue of the JOURNAL was published the call for volunteers for the unit with full statement of the details of requirement.

On May 22 the totals of the principal American relief funds for the European War reached the following amounts:—

	N. Y.	N. E.
Belgian Fund.....	\$1,036,700.62	\$250,100.70
Red Cross	494,032.71	134,460.51
American Ambulance	388,743.00	
Polish Fund	77,699.35	45,988.24
Serbian Fund	64,670.77	30,266.25
Depage Memorial		624.00

BOSTON AND NEW ENGLAND.

NORFOLK DISTRICT MEDICAL SOCIETY.—At the 65th annual meeting of the Norfolk District Medical Society, held May 11, at the American House, Boston, the following officers were elected: President, Dr. Matthew Vassar Pierce of Milton, Harvard A.B., 1877, Harvard Medical School, 1880; vice-president, Dr. Thomas F. Greene of Roxbury, Tufts '94; secretary, Dr. Bradford Kent of Dorchester, Harvard '02; treasurer, Dr. George W. Kaan of Brookline, Harvard '90.

PASSAGE OF MEDICAL REGISTRATION BILL.—On May 12, by a vote of 120 to 77, the House of Representatives of the Massachusetts General Court passed to be engrossed the bill providing that no person shall be admitted to the practice of medicine in Massachusetts who is not a graduate of a duly chartered medical school with power to grant degrees.

MASSACHUSETTS PHYSICIAN SAILS FOR SERBIA.—On May 15, Dr. Stanley H. Osborn of Peabody, Mass., sailed from New York aboard the *Athenia* to serve at Nish and Belgrade under Dr. Richard P. Strong in the Rockefeller Commission for the eradication of typhus fever. He graduated from Tufts Medical School in 1914.

ELECTION OF DR. WALCOTT.—At the annual meeting of the American Academy of Arts and Sciences, held in Boston on May 14, Dr. Henry P. Walcott, Cambridge, Mass., was elected president for the ensuing year.

REPORT OF THE CHILDREN'S HOSPITAL.—The forty-sixth annual report of the Children's Hospital, for the year 1914, contains the following statistics: Number of patients treated 2585, daily average 104; new patients treated in the out-patient department, 6776; number of operations, surgical 652, orthopedic 444, throat 788; social service department new cases, 936. The new hospital was fully occupied by the month of June. During the months from September to December the number of patients treated in the wards increased 44% and the out-patient visits increased 36% in comparison with the same months of the previous year, demonstrating the greater facility of the new hospital in treating cases with its added equipment and increased capacity. Legacies and endowments received during 1914 amounted to \$64,014.40.

REPORT OF THE INFANTS' HOSPITAL.—The recently published report of the Infants' Hospital contains a record of its service from March 3, 1914, when the new Thomas Morgan Rotch memorial building was opened, to Jan. 1, 1915. During that time 303 babies have been received in the wards. The charitable work of the hospital,—caring for the sick babies of the poor,—is badly handicapped for lack of income. During the summer months the hospital was compelled to refuse admission to two sick babies every day, and the number has increased to three. As a means of increasing the income of the hospital various rearrangements were made to increase the accommodation for paying patients, and over \$2500 was netted in this manner. There is a class of nursery maids carried on at the hospital, which provides a six months' course of training. The wet-nurse directory, formerly under the auspices of the Massachusetts Babies' Hospital, has been taken over by the Infants' Hospital. Forty-nine wet-nurses were admitted and forty-two were placed in families. That the work of the hospital should be restricted because of lack of funds, in a city where hospital provision for infants is limited, is deplorable, and it is earnestly to be hoped that adequate support may be forthcoming during the present year.

MILK AND BABY HYGIENE ASSOCIATION.—At the latest meeting of the board of trustees of the Milk and Baby Hygiene Association the following officers were elected: chairman, Charles E. Mason; secretary, Benjamin Loring Young; treasurer, F. Abbot Goodhue. George R. Bedinger, director, reported that during the first four months of 1915 the association cared for 2516 babies.

A SECOND EPIDEMIC OF TONSILLITIS IN DORCHESTER.—In the issue of the JOURNAL for May 6 we commented editorially on an epidemic of streptococcus sore throat then prevalent in the Dorchester district of Boston. There is at present a second similar, but smaller, epidemic in the same district, comprising about one hundred and fifty cases. It is believed by the board of health that the source of infection in these cases has been traced to two dealers dispensing unpasteurized milk obtained from dairies in Canton, Milton, Randolph and Stoughton, Mass. Pasteurization of this milk supply has now been ordered. It will be instructive to observe whether this procedure is followed by a cessation of the epidemic. The source of infection in the previous epidemic has not yet been authoritatively determined.

INDUSTRIAL THERAPY IN STATE INSANE INSTITUTIONS.—At the meeting of the American Medico-Psychological Association in Virginia from May 11 to 14, was shown a representative exhibit of the work of the state institutions under the control of the Massachusetts State Board of Insanity. This exhibit included a series of 353 articles,—brushes, brooms, boots, rugs, and examples of string work, basketry, embroidery, leather work, metal work, pottery and weaving. All these articles were made by inmates of the Massachusetts State Insane Hospitals and illustrate the methods of industrial therapy there employed. The recent bulletin (No. 9) of the Massachusetts State Board of Insanity for May, 1915, describes the further progress in application of this method. At the Westborough State Hospital the industrial workroom has been transferred from the basement, where the work was done before, to a large, airy and sunny room on the third floor. At the Grafton State Hospital the weaving of overall cloth has been added to the other industries.

FATAL POISONING BY AMERICAN WATER HEMLOCK.—The recently published monthly bulletin of the Massachusetts State Department of Health for February, 1915, contains a report of a case of fatal poisoning by the root of the American water hemlock, eaten by a farm laborer while at work in Milford, Mass. The poisoning was symptomatized by nausea, vomiting, vertigo, widely dilated pupils, convulsions, unconsciousness, coma and death in one hour after ingestion, the amount eaten being about an ounce. On investigation the plant proved to be the American water hemlock (*cicuta maculata*), commonly known as spotted cowbane or beaver poison.

"It is one of the commonest of our meadow and swale plants, and variously referred to as water hemlock, wild hemlock, cowbane, beaver poison, musquash root and muskrat weed. In several instances children have been fatally poisoned by eating its roots, which have been termed 'children's bane.' The plant is often erroneously referred to as 'wild parsnip.' It is closely

allied to the less common and somewhat less virulent poison hemlock (*Conium maculatum*) with which Socrates was put to death. A related plant, *Sium cicutaefolium*, which grows with *Cicuta* or in similar habitats, has similar roots which were eaten by the Indians. In the winter and spring, when the roots are well filled, the Indians distinguished the two plants by the old stalks. The stems of *Cicuta*, the poisonous plant, are cylindric and quill-like, those of *Sium* strongly corrugated or furrowed.

The roots of the American water hemlock consist of several oblong, fleshy tubers, spreading out from the base of the stem. They are among the first green substances to appear in the spring, and are eaten chiefly by herbivorous animals. They are mistaken by human beings for parsnips, because of their odor and texture, artichokes, sweet cicely, horse-radish, or other edible roots."

In the year book of the United States Department of Agriculture for 1896 is reported another similar case of poisoning by the American water hemlock.

NEW HAMPSHIRE STATE MEDICAL SOCIETY.—The 124th annual meeting of the New Hampshire Medical Society was held in Memorial Hall, Concord, N. H., on Wednesday, May 19. The first meeting of the house of delegates was held the previous evening at the Eagle Hotel. The general sessions on Wednesday were opened at 10 a.m., with an address by the president, Dr. Herbert K. Faulkner of Keene. At 11 a.m. the simultaneous sessions of the sections on medicine and surgery were opened and a number of interesting papers were presented by members of the society. Another general session was held at 2 p.m., at which there were addresses by Dr. Allan J. McLaughlin, Massachusetts State Commissioner of Health, on "Preventive Medicine," and by Dr. John B. Blake of Boston on "Surgery of the Spleen." The oration in medicine was delivered by Dr. Alexander Lambert of New York on "The Equilibrium of the Circulation" and the oration in surgery, by Dr. William S. Bainbridge of New York on "Chronic Intestinal Stasis." Between the morning and afternoon sessions the women members and the wives of visiting members were entertained at luncheon at the Memorial Hospital by the hospital trustees. The annual banquet was held at the Eagle Hotel at 7 p.m., preceded by an informal reception. The usual exhibition of books, surgical appliances, drugs and foods was held during the meeting in the basement of Memorial Hall. On the date of the meeting the New Hampshire Historical Library, the Friendly Club, the Woman's Hospital, the Margaret Pillsbury Hospital, and the New Hampshire State Hospital were opened for inspection and rest.

Massachusetts Medical Society.

SOCIAL SERVICE INSTITUTES.—Following the joint meeting of committees from the Massachusetts Medical Society and the Massachusetts Federation of Churches, recently reported in the JOURNAL, there have been three social service institutes arranged by the Federation of Churches, at each of which a physician has been given a prominent part in the program. The first was at Springfield on March 10, the second at Middleboro on April 14, and the third at Littleton on April 26.

In each meeting the stress of the address has been upon the need of a trained health officer in each city and town.

Miscellany.

VETO OF THE CLEAN MILK BILL.

THE following represents in part the text of Governor Walsh's message to the State Senate on May 20 conveying his veto of the so-called Labor Clean Milk Bill, which is commented upon editorially in another column of this issue of the JOURNAL:—

"Although from its title the bill appears to be mainly aimed at the distributors of dairy products, a study of its provisions will show that its heaviest penalties are reserved for the producer, who, in addition to the fine and imprisonment to which dealers are made liable, is exposed to the risk of being obliged to choose, on a very few days' notice, between undertaking a possibly heavy expense in order to conform his buildings to an undetermined sanitary standard discretionary with either the State Board of Health or a local board, or as an alternative accepting his sentence and abandoning his business.

"Such being the case, it is necessary to consider whether a measure so drastic is really needed for the protection of the public health, and whether, on the other hand, it might not reasonably be expected to aggravate the very evil which its advocates aim to remove.

"I yield to no one in my anxiety to secure for the children of our state a pure and abundant supply of milk at a reasonable price. This object, however, I am thoroughly convinced, cannot be obtained by further penal legislation, but only by encouraging and developing the production of nearby milk through constructive legislation, such as I hoped would be worked out and submitted to the Legislature by the special commission for which I asked earlier in the session.

"My specific objections to the present bill are these:—

"First: That the State Board of Agriculture and the Dairy Bureau, the authorized representatives of the agricultural interests, are opposed to its enactment.

"Second: The State Department of Health has not initiated any legislation on the subject, and should be given time and opportunity to study the question before further legislation is adopted.

"Third. As the bill carries no appropriation and provides no new facilities for inspection, but merely exposes producers and dealers to new and ill-defined perils, it tends to terrorize the farmers and milk-producers of the state, without adding any protection to the consumer, and can have no other effect in my judgment than to drive many self-respecting dairy men out of business and materially increase the price of milk.

"Fourth: It is a well-established fact of bacteriology that disease germs multiply at almost incredible rates in milk and cream at ordinary temperatures when once introduced in them, and that it is therefore of the utmost importance from a sanitary standpoint that milk should reach the consumer in as few hours as possible after its production. This bill discourages the production of nearby milk, tends to increase the average of milk consumed, and thereby increases rather than lessens the danger to the public health.

"Fifth: The bill discriminates against Massachusetts producers, since if convicted, a Massachusetts man becomes a criminal, while the out-of-state man escapes with the exclusion of his product from the state, a matter already fully provided for in Chapter 755 of the Acts of 1914.

"Sixth: I find experts of the highest standing agreed that dairy inspection alone fails to provide any adequate protection against the spread of disease in milk, while laboratory tests of the product itself have proved of great value. This bill in my judgment will not improve the quality of our milk supply one iota, since it deals only with the conditions of production, without any attention to the actual quality of the product.

"Seventh: The farmers of the commonwealth are as honorable and law-abiding a class of citizens as any other, and this legislation is certain to penalize and humiliate them in a way that they have not deserved. The milk produced by our farmers is as clean and wholesome as that produced in any other part of the country, and they should not be compelled to submit to inspection and regulation that are unnecessary and that do not take into account the quality of the milk product itself.

"Eighth: There is already an ample amount of penal and regulative law upon this subject. The Bureau of Animal Industry is empowered and directed to see to it that milch cows are free from disease and stabled under sanitary condi-

tions. I have yet to learn that any local board has failed to do its duty under the present laws.

"As a whole, this bill affords an apt illustration of the difficulties that are likely to result when private individuals or organizations, however zealous and well-meaning, attempt to shape legislation in the public interest without the aid and guidance of the state departments created and maintained for the express purpose of protecting these very interests.

"It is argued that the danger of unjust prosecutions under the pending bill is obviated by the provision giving immunity unless the person complained of has first been warned against committing the offence; but as the bill is worded it seems that the warning need only be a general one not to deal in 'any such milk,' and that a person who has once received such a general warning would be fully liable to punishment if any milk subsequently found in his possession could be proven by its bacterial content or on direct evidence to have been produced or handled under improper conditions, even though he neither had, nor from the nature of the case could have, any knowledge or warning of the existence of such conditions affecting that particular milk.

"We have a state department of health, headed by a physician of world-wide reputation in this very field of the prevention of communicable diseases, aided by an expert of nationwide reputation on communicable diseases, and an advisory council whose fidelity and ability are unquestionable. If this board, after a careful study of the entire situation, shall consider additional legislation advisable, it will doubtless recommend a thoroughly digested measure to the next Legislature, free, it is to be hoped, from the glaring faults of the pending measure and several of its predecessors.

"Clean milk for the babies and invalids is a great necessity, but legislation hostile to the dairy industry, without obtaining clean milk, may prevent thousands of babies in the Commonwealth from receiving any milk at all because the price may become prohibitive to our poor people.

"The decline in this industry has been constant and alarming, the number of milch cows is yearly decreasing, and I am convinced that it is in a large part due to the fact that constant legislative agitation has alarmed our farmers and made the business for the producer and small dealer not only unprofitable but almost discouraging.

"What we need in Massachusetts is not more inspection or penalizing, but laws tending to educate and encourage the dairy industry in order that we may have not only clean milk but an abundance of it at reasonable prices."

"I feel certain that many of the communications and endorsements that have come to you and to me in favor of this legislation have been influenced by the very name with which the bill

has been labelled in the popular mind, namely, 'The Labor Clean Milk Bill.' By using the words 'labor' and 'clean milk' a sentiment can be aroused in any community in favor of proposed legislation.

"I am thoroughly convinced that the measure is without merit and involves a very serious injustice to a large element of the community engaged in an honorable and legitimate occupation. No results will follow its enactment to improve the condition of milk in this commonwealth, but on the contrary any such legislation is certain to injure the dairy industry materially and lead to increased cost in the price of milk."

AMERICAN ACADEMY OF MEDICINE.

THE fortieth annual meeting of the American Academy of Medicine will be held at San Francisco on June 25 to 28, in conjunction with the meetings of the Pan-American Medical Congress and the American Medical Association. The presidential address will be delivered by Dr. Woods Hutchinson, and the annual address on "The Relation of Medicine to the Peace Movement," by Dr. David Starr Jordan. There will also be addresses by Dr. Rupert Blue on "The Prevention of Oriental Diseases in the Ports of America"; by Dr. Victor G. Heiser on "Hookworm Disease and Its Relationship to Immigration and Commerce in the Philippines"; by Dr. W. C. Rucker on "The Transmission of Typhoid on Trains and Steamboats"; by Dr. W. A. Sawyer, of Berkeley, Calif., on "The Disease Carrier on Train and Steamboat"; and by Dr. Richard P. Strong of Boston on "The Need of Medical Conquest for the Establishment of Commerce."

At its previous annual meeting, on June 22, 1914, the Academy, which was founded as a society for the study of questions of social medicine, adopted the following report of its committee on policy with reference to its future.

"The American Academy of Medicine has specialized in medical sociology for the last eight years. The work done has been of the greatest importance. The publications of the academy have won a high place and are in constant demand. The revised constitution and by-laws make it possible for us so to extend our membership as to include as fellows all physicians who are interested in this phase of medicine and, in associate membership, all workers in the field of sociology who recognize that scientific medicine is fundamental to all inquiries and investigations of abnormal social conditions, and that the cooperation of the physician is essential for the successful administration of measures for the correction of conditions which interfere with human efficiency.

"We believe that the field of sociologic medicine is so large that it can only be satisfactorily

covered by a national society of the broadest scope and with the widest conception of the nature of the work before it. We believe that the American Academy of Medicine is the legitimate one to expand into such an organization.

"Therefore your committee recommends that the American Academy of Medicine continue in the field of medical sociology. . .

"Your committee further recommends that the academy take up, together with as many other organizations as can be interested, at least the following phases of medical sociology.

- "1. The child and its relationship to society.
- "2. The medical aspects of education.
- "3. The social inefficient.
- "4. Legislation and medicine.
- "5. Medicine in its relationships to industry, trade and commerce.
- "6. Civilization in its effects on morbidity and mortality."

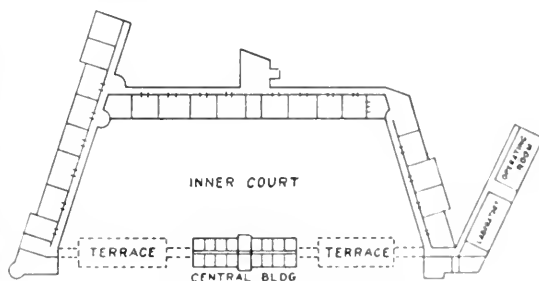

Correspondence.

THE HARVARD UNIT AT THE AMERICAN AMBULANCE IN NEUILLY, PARIS.

PARIS, April 8, 1915.

Dear Mr. Editor: We have been here two weeks and you may be glad to have a few words of our early impressions.

Photographs of the Lycée Pasteur you have seen, but it is a surprisingly large place, and none of those that were circulating at home serve to give an idea of its extent. A better idea may be given by the bird's-eye view which I enclose, taken from a tall apartment across the way on the Boulevard Inkermann. Since Crile's sojourn here the entire third floor is given over to the University Units, and in order that you may have some conception of the space at our disposal, this sketch of the floor plan may help you—for, though admirably adapted for its present purposes, it is a most labyrinthine place, and owing to the wings, one's orientation is readily confused, even after a week's occupancy. This is particularly

Lycée Pasteur, Third Floor Plan.

so because the corridors on the two sides adjoin the court and that on the long side is away from it.

We have supervision of the 18 small wards on this floor with a capacity of 162 beds. Our operating room and laboratory, both of ample size and well lighted, are *au troisième* in the adjoining wing above the chapel, where, I may add, you are Catholic if you face one way and Protestant if you face the other. A very readable book, in the form of a diary, from

Aug. 3 to Dec. 31, *La Guerre vue d'une Ambulance*, has been written by the Aumônier, l'Abbé Félix Kleim.

The present capacity of the hospital is about 500, divided into four services, under Dr. duBouchet, who is surgeon-in-chief and is responsible to the military authorities—for the hospital, as you know, is under a military and not a Red Cross organization—Dr. Blake, Dr. Mignot and ourselves. There are at present some 450 wounded, mostly from the French forces, including those from Africa. There remain a few "Tommies," relics of the battle of the Marne days when this Ambulance was almost a first-line hospital, but there are no longer any wounded Germans, they being sent to special hospitals—to Val de Grace, I believe, and elsewhere; for they require a military guard, and there are uncomfortable stories regarding Turcos and Germans kept under the same roof.

We did not quite overlap our predecessors, for they sailed on the first and, therefore, had to leave two or three days before our arrival. But the wards had been purposely somewhat emptied for us so that we started in with only about 100 *blessés*. Naturally our first visit among them was of extraordinary interest to us on a personal as well as a professional side. Every individual story was so appealing and fascinating as to make it difficult at first to concentrate one's attention on the lesion and the actual condition of the moment—in what engagement the man was injured,

Lycée Pasteur, Neuilly, Paris. Ambulance Américaine.

what he was doing at the moment, with what sort of a missile he was hit, where he got his first aid, through what hospitals and what hands he had gone on his way here from the time he was tagged with a pink or a white ticket at the *Poste de première secours*, how long since he had had his clothes off, since he'd had a bath and so on.

Though there are many exceptions, I should say that the cases fall into three regional groups,—wounds of the upper and of the lower extremities, and of the jaws. There are a number of cranial injuries, some of them of great interest, a ward full of hopeless spinal paraplegias—a sad place—many chest cases also; but the majority of the wounded in a hospital this far from the line at present will fall into the three groups mentioned. We are a little too late to see the frost-bitten or "water-bitten" feet which a few months ago must have been overwhelmingly numerous, for there are still a number of them not yet entirely recovered which are holding over; all sorts of tender feet with acroparaesthesias and erythromelalgia-like phenomena which would make an interesting study in themselves. A man with deformed toes, due to wearing *sabots* in childhood, as is the case with one of our patients, wearing none too well fitting army shoes, tight puttees in addition, with some resultant venous stasis, standing for hours or days in cold water or mud in the trenches and without having his shoes off for weeks perhaps—well you can imagine the result. Good feet to get about on and good teeth to crunch crusts of bread are two of the essentials to efficiency. Without these a soldier doesn't

get back at all, whereas a few *balles de fusil* can go through him and he's in the line again after a few days.

Even among the wounded in our wards one sees every kind of a fracture in every situation from all sorts of missiles—or from none at all, for men may be injured in this dangerous trade of warfare in many ways: as by the falling in of arborescent trenches when blown up by a shell, without being actually hit themselves. One of our patients, for example, has some broken ribs from the kick of a horse; another a broken jaw from the butt end of a musket, but the majority have "amassed souvenirs in the shape of lead and spears,"—you remember Kipling's "Father Bobs" I am sure,—shrapnel, pieces of *obus*, often of amazing size, pointed German jacketed bullets—sometimes even the solid brass French bullets—and all other conceivable things. A routine x-ray examination is of course necessary and the Roentgenological department, like all other departments here for that matter, is admirable, being under the direction of an expert, Dr. Jaugeas, who, from the first, has given almost his entire time to the work—and this is the rule, not the exception. Cutler sent one of our cases to him the other day, needlessly I thought, for the man had a little wound over the mastoid which had nearly healed and there were no especial symptoms. The x-ray disclosed an unsuspected shrapnel ball in the cerebellum. His record stated that he had been hit by a small fragment of shell which had been removed at the *Ambulance de première ligne*.

There are naturally all sorts of bizarre wounds. Thus, one of the men, with a wound through the face, jaw and neck, where the bullet emerged after dividing the cervical sympathetic, received from the same projectile, as was supposed, a compound fracture of the acromion where the x-ray showed what was thought to be the jacket of the bullet; but it proved to be the deformed metal button of his shoulder strap which had been set in flight by the original ball after it had traversed his head. Stories of these bizarre effects might be multiplied without end.

The explosive fractures of the long bones are, of course, in many cases dreadful, and those from shrapnel, and fragments of *obus* inevitably infected, but I fear that your correspondent who signs himself "S." has greatly exaggerated the helplessness of the surgeon in these cases. The mortality is really very low and the amputations relatively infrequent even when there is gas infection. The story is of course different when there is actual *gangrène gazeuse*, which apparently is an accompaniment of great tissue destruction with associated circulatory disturbances from thrombosed and damaged vessels. But, at the best, the healing of these bad fractures is a long tedious affair with the almost inevitable osteomyelitis and necessary wait for separation of fragments. Then too, almost every case has some associated paralysis. This is particularly true of the upper arm fractures in which a musculo-spinal paralysis almost always occurs, even when the nerve has not been touched, and indeed actual divisions of the nerves are comparatively rare. I estimated during our first few days that nearly 50% of our wounded had a concomitant neurological lesion of more or less major type. Then, too, for Osgood in particular, among the members of our Unit, there are problems of absorbing interest, for almost every patient has some joint trouble from long fixation, or some deformity which is capable of alleviation in his skilful hands, and he has been very busy in consequence.

It is a great regret that we did not succeed in bringing a dental surgeon with us, for of all the opportunities of an unusual sort which the hospital presents, this is, I think, the greatest. Under the direction of Dr. Hayes the dental department at this Ambulance has struck out into entirely new fields and has done such admirable work that the authorities send here a great many of the bad fractures of the upper or lower maxillae. There must be at least 50

of them now under treatment, from poor creatures with their entire lower jaw blown away to fairly simple fractures with the teeth out of alignment. Dr. Hayes has indefatigably given practically his entire time since August to this work and had a number of men associated with him and needs more. It is a form of major surgical work assumed by the dentist which places him on a level with the surgical specialist in any other line, and the work cannot be too highly praised. The U. S. Government should make every effort to send over our army surgeons to receive instructions in this work if in no other, for it is important and new.

The effectiveness of our contingent has been greatly crippled by the loss of Strong who, though here for 10 days and giving us as much of his time as possible meanwhile, was nevertheless occupied intensely on matters relative to the preparation of his expedition to Serbia. We had planned to make some special studies of the gas infections, a problem the importance of which we did not fully realize before leaving home and which Rogers and Benet will attempt to carry out on the lines Strong has laid down. The opportunity is exceptional, for no one seems as yet to have even culturally differentiated the various strains with which these wounds are infected. They are all grouped as *B. perfringens* rather than as varieties of the *B. aerogenes capsulatus* as Americans would like to see them.

The expedition of which Strong will doubtless be given the leadership has assumed proportions of an international scope and I may say that nothing but praise of him is heard on all sides—not alone for the sacrifice he is making but for the evident capacity of leadership and quick grasp of situations which he has shown. The Sunday before he left I had the good fortune to go with him in a military motor up to Amiens and from there along back of the line in several places on a *laissez-passer* of broad scope from the war office, which gave us an exceptional chance to see the various grades of hospitals and the system of transportation of wounded from those at the first line back to the base. They are at present getting typhoid well under control through compulsory vaccination, which was not adopted till the end of the year. One of the physicians estimated that there had been 70,000 in the French army in the last months of 1914. There were about 4000 at the large hospital at Amiens alone.

In these front line hospitals, too, one sees the severe cases—cranial, spinal, and abdominal which cannot be evacuated to the more remote hospital centres. The mortality of the severely wounded is, of course, high, whereas at the Ambulance at Neuilly, where less severely wounded cases are now received, there have been, I believe, only 81 fatalities, most of them occurring in the early months during the fighting along the Marne close at hand. Our first admission on April 1st was a man with *obus* injury of the occiput, causing hemianopsia, his number being 1387, which would make a percentage mortality of 17 for the entire series—high enough surely. With the present run of cases it would, of course, be very much lower.

I think our men have all done very well and I am sure the expedition will prove a credit to our hospitals and the University, and it is possible that we may be able to secure valuable material for the Warren museum, already rich in pathological material from former wars. Whatever misgivings we may have had before leaving of the wisdom of our coming, vanished the day of our arrival; and I think the Ambulance officials are appreciative of our desire to make our work as effective as possible. Greenough has managed our affairs with great executive ability and by common consent has been made our visiting chief. Five of the men, Cutler, Collier, Barton, Wilson, and Petersen, are "living in" at Neuilly, and the rest of us are comfortably housed in Paris not far away.

One of the French surgeons who was looking on at an operation the other day in which Boothby was

giving the anesthetic intranasally with the Connell apparatus, said to me "We know nothing about giving anesthetics in France." It is a satisfaction to feel that we may be helping in this respect and indeed our operating room, owing to the installation of this apparatus, has already become a centre for operations on the head and face. Crile also helped the Ambulance greatly in this respect and his anesthetist, Miss Hodgins, is still here giving instruction in gas-oxygen administration.

Well, Mr. Editor, I have scrambled through this letter, which I shall hardly venture to reread, with much that I would like to say still unsaid. In this place, unquestionably the best of the four or five hundred auxiliary hospitals established in Paris, there is a most amazing aggregation of talent, and to follow a poor wounded devil in his dirty uniform, brought in in a Ford ambulance by an upstanding young ambulance driver—a college graduate likely enough—from some distributing point, to see him recorded by the indefatigable Mr. Kollman, then stripped and given a bath, well lathered in a tub by one James Jackson, formerly engaged in some mercantile pursuit and jokingly dubbed K.C.B., then taken to his bed, where he quickly falls into an exhausted sleep, by orderlies who may be young architects or artists or sons of aristocratic families, shaved and clipped by a barber who accepts no fee, cared for in countless ways subsequently by attractive, skilled and effective attendants, men and women of all walks, but serving with whole-souled devotion—it all is a most creditable thing for American enthusiasm and prompt action to have put through: and its accomplishments and effectiveness will justify all the support it has so generously received and will continue to receive from home.

And of the French wounded themselves too much cannot be said in praise. They are as a whole the most uncomplaining, courageous and appealing lot of men that can be imagined and well deserve all that anyone can do for them.

Sincerely yours,

HARVEY CUSHING.

POTASSIUM PERMANGANATE: ITS COOLING EFFECT UPON THE SKIN.

Boston, May 12, 1915.

Mr. Editor: Summer is coming, and with it is sure to come a certain amount of hot, sticky weather. This sticky, high humidity heat affects the human in one of two ways, according to whether he or she is a thin carnivore or a fat herbivore. The carnivore who perspires little or not at all suffers from headaches and prostration, while the herbivore sits placidly amid streams and puddles of perspiration, his worst suffering perhaps being due to chagrin at the rapid ruination of erstwhile immaculate collars and cuffs. Gregg has recently remarked upon this type difference to humid heat, as observed during a residence in the Philippines. To put the two types upon something like an equality of discomfort, the carnivore must be induced to perspire, a phenomenon perhaps most easily accomplished by the use of judicious amounts of alcohol: by judicious amounts is meant not more than a sherry glass of claret, madeira, or other similar beverage, taken at the oftenest not more than once in every four hours and perhaps best only with or after meals or three times daily during the excessively hot weather. Having thus induced perspiration and relieved the headache of the carnivore by internal medication, the question arises, can anything further be done to promote comfort in the dog-days? This question assumes that the usual methods have been exhausted.

The answer is a decided yes. If, under the conditions above stated, one wishes to experience in the hottest and wettest weather available, a sensation as of a drop in temperature of say ten degrees with cor-

responding relief from the effects of humidity, it is necessary only to take a bath in or rub down with a weak solution of potassium permanganate. This may be followed by a shower or wash with plain water. The result will justify the effort of the procedure, and it is especially valuable as a means of promoting sleep at night.

This proposition very likely is known to many, but it is at least in this case the accidental discovery of the author and seems not to be known to any of his medical friends unless through personal conversation on the subject. For this reason, and with a marked increase in comfort so easily obtainable, it has seemed worth while to present this simple expedient in the hope that a few persons and particularly invalids may thereby receive the benefit from its application.

Arriving one day on an errand of medical necessity at Batavia, some years ago in the midst of the Javanese summer, the writer found the climate both hot and wet as was to be expected. One of the provisions for the entertainment of the tourist was, and doubtless still is, endemic cholera. This necessitated certain precautions. For instance, sulpho-naphthol was used rather freely upon floors, and fruit for the hotel table was always exposed to live steam. Also, the bath water always contained enough permanganate to give it a good reddish-brown tint. According to the custom of the country, a splash bath is taken: one stands upon a wooden grating and with the aid of a dipper throws over one's shoulders from a large tub at the side which is refilled daily. Permanganate is used in order to dampen the ardor of what germs may be present in this tub of water. All this is perfectly proper. The surprising feature of the use of this solution was its immediate cooling effect, lasting for some hours. At first it was dubious if the permanganate was really the active agent in producing the sensation of the drop in temperature, but repeated use of the solution for bathing purposes left no room for doubt, and recurring summer heat, both in this country and in Europe, has only provided opportunity for confirming the experiment and proving that permanganate has a very active value as a cooling agent.

The fact has been sufficient, but doubtless the mode of action is at least in part by the removal of all grease from the skin with better opportunity for loss of heat from the body. To try the experiment is to be convinced. It is only necessary to buy a few crystals of permanganate and make a saturated solution. Pour enough of this solution into a wash bowl to give the water a pale pink or reddish tint, rub down with a wash cloth, and follow with a shower or bath as desired. A solution strong enough to be effective can be used without discoloring the receptacle, or if necessary any stain is easily removed by the use of a little oxalic acid solution.

Potassium permanganate in weak solution is a valuable wash for external application in hot humid weather. Its use in conjunction with the customary bath greatly promotes comfort by day and sleep by night at a time when both comfort and sleep are at a premium.

Very truly yours,

JOHN BRYANT, M.D.

CORSETS, PTOSIS, AND SACRO-ILIAC STRAIN.

78 MARLBOROUGH STREET, BOSTON.

May 13, 1915.

Mr. Editor: I have just read with much interest the communication from Dr. Eben W. Fiske in your issue of this date in regard to my recent article in the JOURNAL on corsets, ptosis, and sacro-iliac strain, and cordially appreciate the courtesy of his criticism and his temperate statement of the position which he takes. I would not for a moment presume to dispute or differ with the opinion of Dr. Fiske, or of any other orthopedic expert, on the mechanics of the

production of postural defects or of the modes of their correction. My paper was intended merely to present my personal experience and observation in dealing with such cases, especially in women in a gynecological clinic.

In your editorial note to Dr. Fiske's letter you called attention to one point in my paper which, through incomplete quotation, may have been misapprehended. My classification of corsets into those that lace in front and those that lace *only* behind, was not intended to condemn corsets, of which there are several styles, which lace both front and back. Many patients prefer a corset with a laced back to one with a solid back on account of its being cooler; and I find no objection to such a corset provided it laces also in front. It is my belief, however, that only the front laces, and never the back laces, should be used, at least by the patient, for adjustment of the corset after it has been put on. From my experience I am not disposed to believe it possible for a patient, in any posture, to adjust her own corset as effectively with a back lace as with a front lace, though I would not for a moment deny that this may be done by an expert surgeon.

Neither can I bring myself to believe, in spite of Dr. Fiske's exposition, that it is possible to correct ptosis as effectively with any corset applied in the standing posture, as in the recumbent posture. The flesh of the abdominal wall may be lifted by the former method, but it is not this sagging flesh which constitutes the ptosis. Prolapsed abdominal viscera cannot thus be raised. For their replacement it is essential that gravity, by elevation of the hips in a recumbent posture, should first be employed to transfer the sliding viscera upward towards the diaphragm. The corset, properly applied in this posture, then splints the abdominal wall, so that the viscera cannot again prolapse when the patient stands up. At the same time, I believe such an application of a good corset, by splinting the pelvis, relieves the pain of sacro-iliac strain and, if combined with proper shoeing, tends to correct the postural defect, which has contributed to the production and establishment of the ptosis.

As I have said, my original paper was intended merely to present personal gynecologic experience and observation, not to lay down categorical or universal rules of procedure. It is obvious that conditions differ widely in different classes of patients and, as Dr. Fiske has felicitously pointed out, that different surgeons obtain equally good results by diverse methods. I am exceedingly grateful to Dr. Fiske for his valuable contribution to the discussion of this question and shall feel more than satisfied if my imperfect presentation of the subject may lead to a wider interest in and recognition of the importance of conditions of ptosis and postural defect as complicating or simulating other pathologic complexes.

Very truly yours,

ROBERT M. GREEN, M.D.

THE CHANGSHA YALE HOSPITAL.

CHANGSHA, CHINA, April 6, 1915.

Mr. Editor: May I ask the favor of your courtesy to state something of the situation in medical education in China. The Medical Commission of the Rockefeller Foundation has recommended support by the Foundation of four centers for medical education in China. One of these four is the Hunan-Yale Medical College and Hospital at Changsha, the capital of Hunan Province. This institution represents a joint agreement between Yale-in-China and a society of Chinese representing the Hunan government, for the development of a first-class school of medicine, nursing schools for men and women respectively, a modern teaching hospital, and a diagnostic and research

center for central China. The hospital, medical preparatory school, and nurses' schools are now in operation. The standards are the highest possible. The aim is quality and not quantity of work.

The support of the Rockefeller Foundation and the rapid growth in Changsha make a large increase in the medical and nursing staff necessary within the next two years. Both laboratory and clinical branches require trained men. Dr. Hume, the head of the Yale-in-China medical staff, will be in the United States until August 1, and will welcome inquiry from qualified applicants, or from men now graduating in medicine or in hospital positions, who wish to investigate these great opportunities in the Orient. Address, Dr. E. H. Hume, 5 White Hall, Yale University, New Haven, Conn. The scope of the Human-Yale institution is not limited to Yale men by any means.

Very truly yours,

ALFRED C. REED, M.D.

BELGIAN PHYSICIANS' RELIEF FUND.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE THREE WEEKS ENDING MAY 15, 1915.

April 24, Asst. Surgeon A. E. Man, M.R.C., detached, Naval Medical School, Washington, D. C.

April 26, P. A. Surgeon E. U. Reed, detached, Marine Recruiting Station, Detroit, Michigan, to *Maine*.

April 27, P. A. Surgeon T. G. Foster, detached, Naval Disciplinary, Barracks, Port Royal, S. C., to *Chester*.

Asst. Surgeon J. T. Boone, detached, Naval Medical School, Washington, D. C., temporary duty, Naval Training Station, Norfolk, Va.

April 23, Surgeon J. D. Manchester, to Naval Hospital, Portsmouth, N. H.

April 30, Surgeon J. M. Brister, detached, *Kearsarge* to *Alabama*.

Asst. Surg. M. H. Sicard, M.R.C., commissioned April 12, 1915.

May 1, Surgeon J. R. Dykes, placed on retired list of officers of the Navy, from April 27, 1915, to home.

May 5, Asst. Surgeon W. A. Stoops, M.R.C., detached, Naval Hospital, New York, to temporary duty, Naval Hospital, Newport, R. I.

May 8, Medical Director, C. H. T. Lowndes, commissioned from April 18.

P. A. Surgeon T. G. Foster, detached, *Chester*, to Atlantic Reserve Fleet.

P. A. Surgeon H. L. Brown, detached, *Alabama* to *Chester*.

May 11, Surgeon C. E. Ryder, to Naval Training Station, Great Lakes.

Surgeon R. R. Richardson, detached, Great Lakes Training Station, Naval Hospital, Las Animas, Col.

P. A. Surgeon D. C. Walton, detached, Academy, June 7, 1915, to *Ohio*.

Asst. Surgeon S. D. Hart, detached, Naval Hospital, Las Animas, Col., to wait orders at Washington, D. C.

NOTICES.

DOCTORS FOR DUTY IN A BRITISH BASE HOSPITAL.

Harvard, Columbia and Johns Hopkins Universities propose to provide a surgical unit to take charge of a base hospital for British wounded, and for that purpose there is desired a staff of thirty-two surgeons; sixteen of these will preferably be well trained fourth-year graduates or house-officers having just completed a surgical service. The expedition will start between June 5 and 15. The Harvard contingent will take the first detail for a minimum service of three months. Preference will be given to men willing to stay six months.

The service will be either in England or in France, depending upon exigencies. Transportation both ways will be paid, and men will be given regular army pay. Men wishing to join the expedition will please apply in writing to Dr. Edward H. Nichols, 294 Marlboro Street, or to Dr. C. A. Porter, 254 Beacon Street, or to Dr. Wm. E. Faulkner, 290 Marlboro Street, stating their age, medical education and surgical training.

NURSES FOR DUTY IN A BRITISH BASE HOSPITAL.

Harvard, Columbia and Johns Hopkins Universities propose to provide a surgical unit to take charge of a base hospital for British wounded, for a period of six months. The expedition will start probably sometime between the first and the fifteenth of June.

For this unit there is desired a staff of seventy-five trained nurses, consisting of one matron, twenty-six sisters (head nurses), and forty-eight ward nurses.

Nurses will be paid regular army rates: sisters, "head nurses," 50 pounds per annum; staff nurses, "ward nurses," 40 pounds per annum. Free transportation to and from the hospital, probably an American ship will be provided.

The service will be for a minimum period of three months, and preference will be given to nurses agreeing to serve for six months. The service may be in England or in France, depending upon exigencies.

Nurses wishing to join this unit, will please apply in writing to Dr. E. H. Nichols, 294 Marlboro Street, Boston, stating their training and experience with references to doctors for whom they have worked. Nurses who have had special operating room experience, will please so state.

SOCIETY NOTICES.

MASSACHUSETTS SOCIETY OF EXAMINING PHYSICIANS AND SURGEONS.—Meeting at the Boston Art Club, May 27, 1915. "Unusual Cases of Intracranial Hemorrhage."

Speakers: Drs. G. B. Magrath, Timothy Leary, Wm. C. Whitney.

J. H. STEVENS, M.D., *Secretary*.

HARVARD MEDICAL ALUMNI ASSOCIATION.—At the coming meeting of the American Medical Association in San Francisco there will be a table d'hôte luncheon at the University Club, the date to be announced later, for members of the Harvard Medical Alumni Association. Dr. William P. Lucas of the University of California, San Francisco, is in charge of the arrangements.

A. B. EMMONS, 2d, M.D., *Secretary*.

PSYCHOPATHIC HOSPITAL MEETING.

On May 27, from 4 to 6 p.m., there will be held at the Psychopathic Hospital, 74 Fenwood Road, Boston, a meeting on the subject of neurosyphilis, Dr. Abner Post presiding. The program will consist of a discussion of social service methods and results by the staff of the out-patient and social service department, of clinical diagnosis by Dr. H. C. Solomon and other members of the staff and of post mortem studies by the members of the staff with the aid of the pathological service of the State Board of Insanity.

APPOINTMENTS.

AMERICAN COLLEGE OF SURGEONS.—*Dr. John G. Bowman* has been appointed director of the American College of Surgeons, with executive offices at 30 North Michigan Avenue, Chicago.

AMERICAN HOSPITAL ASSOCIATION.—*Dr. H. T. Summersgill*, superintendent of the University of California Hospital, has been appointed to succeed the late Dr. W. O. Mann of Boston as president of the American Hospital Association.

HARVARD UNIVERSITY.—*Dr. Richard Pearson Strong* has been appointed regular professor of tropical medicine.

MASSACHUSETTS STATE BOARD OF LABOR AND INDUSTRIES.—*Dr. Thomas F. Harrington* of Boston, at present director of school hygiene in the Boston Public Schools, has been elected deputy commissioner of labor and industries in the Commonwealth of Massachusetts.

RECENT DEATHS.

DR. WILLIAM H. FORWOOD, who died on May 12, at Washington, D.C., was born in Delaware in 1838. He received the degree of M.D. from the University of Pennsylvania and in 1861 entered the Northern army as assistant surgeon and served throughout the Civil War. He subsequently saw service in various Indian campaigns and in 1883 was a member of the expedition which explored Wyoming. In the Spanish War of 1898 he located the military hospitals at Savannah, Ga., and at Montauk Point. Prior to 1891 Dr. Forwood, who had then attained the rank of colonel, was chief surgeon of the department of California. Subsequently he was promoted to brigadier-general, and in 1902 served as surgeon general of the United States Army.

DR. MAX BERNHARDT, professor of neurology at the University of Berlin, died recently in that city at the age of 70 years.

DR. JOHN J. GALLAHUE, who died of cerebral hemorrhage in South Boston on May 17, was born in County Limerick, Ireland, in 1877. He was a gradu-

ate of the Massachusetts College of Pharmacy and of the Harvard Dental School in 1901.

DR. FREDERICK SHURTLEFF COOLIDGE, a fellow of the Massachusetts Medical Society, died at New York, May 14, aged 49 years. He received the degree of A.B. from Harvard in 1887 and that of M.D. in 1891. After serving as house officer at the Massachusetts General Hospital he removed to Chicago where he became professor of orthopedic surgery at the Rush Medical College. Later he removed to Pittsfield, Mass. where he became a member of the staff of the Pittsfield Hospital. He is survived by his widow and one son.

DR. WILLIAM NEILSON, a retired fellow of the Massachusetts Medical Society, died at his home in North Leominster, May 14, aged 75 years. Dr. Neilson was born in Halifax, N. S., Feb. 4, 1840, and was a graduate of the Harvard Medical School in the class of 1872. He was engaged in general practise at Marblehead until 1905, when he was retired and moved to Arlington Heights. He had lived in North Leominster since 1912.

DR. JOHN A. LEE of Boston, who died on May 5 in Framingham, Mass., was born in that city in 1887. He received the degree of M.D. from the Tufts Medical School in 1911 and for a time practised his profession in Dorchester and Roxbury.

ERRATUM.

We regret exceedingly that, owing to the accidental misplacing of a galley, there occurred an error in the arrangement of the paragraphs of Dr. Honeij's article, "A Study of Leprosy," on page 635 of the issue of the JOURNAL for April 29. The first five conclusions of the article are printed on that page instead of with the remainder of the conclusions on page 671 of the issue for May 6. This error was not discovered until too late for rectification, but will, of course, be corrected in the reprints of Dr. Honeij's article.

BOOKS AND PAMPHLETS RECEIVED.

The Gold-Headed Cane by William Macmichael, M.D. Paul B. Hoeber. 1915.

Tables for the Computation of Curves of Autocatalysis, with Especial Reference to Curves of Growth by T. Brailsford Robertson, M.D. Reprint.

Human Motives by James Jackson Putnam, M.D. Little Brown & Co. 1915.

Sleep and Sleeplessness by H. Addington Bruce, A.M. Little Brown & Co. 1915.

The Meaning of Dreams by Isador H. Coriat, M.D. Little Brown & Co. 1915.

CASES OF INFECTIOUS DISEASES REPORTED

to the Boston Board of Health for the week ending May 18, 1915.

	Total Cases.	Non-Residents.*
Diphtheria	82	3
Scarlatina	114	12
Typhoid fever	3	0
Measles	231	3
Smallpox	0	0
Tuberculosis	61	3

The death-rate of the reported deaths for the week was 17.70.

* Non-resident cases are included in the total cases.

Address

PERCIVAL POTT, HIS TIMES AND HIS WORK.*

By ROBERT W. LOVETT, M.D., BOSTON.

ENGLISH surgery in the 18th century was a matter of formalism and system. There was but little inductive reasoning embodied in it and it was rough and cruel. It knew no pathology, as we understand the term, because Morgagni's great work, the foundation of modern pathology, was only published in 1759. Medical instruction was in its infancy, being in the early part of the century largely passed on from one to another, there being no clinical instruction till 1745, except at Leyden, where the great Boerhave, the leading medical figure of Europe, gave clinical instruction and sent his pupils throughout Europe. Toward the middle of the century this form of instruction began in England, and Cullen in 1757 made the innovation of delivering medical lectures in English instead of in Latin.

Surgery at this time was necessarily cruel because it was of the pre-anesthetic period and because of the drastic measures then in vogue. The cautery was heated in the hospital ward when the surgeon appeared for his rounds and dexterity and rapidity of technic were more valued than soundness of judgment or independence of thought. Cheselden, who died in the middle of the century, had performed a lithotomy in 54 seconds, which at that time consti-

tuted the record, and however admirable such a performance may have been it certainly now seems more rapid than would be altogether consistent with safety.

Dolor medicina doloris, that is, pain is the cure for pain, was accepted as the motto of the surgery of the time.

The 18th century was a time when medical science was at a low level, a level lower than that of such allied sciences as physics and chemistry, e.g. in the latter one finds such names as Laplace, Priestly, Lavoisier, Galvani, Volta, Franklin, Fahrenheit, Watt, Fulton, and Stephenson,—names which mark the beginning of a new epoch in their sciences. But in medicine there were few such corresponding men, Morgagni, Hunter and Jenner probably being the most eminent. It was, it must be remembered, a time of mental instability, the best expression of which is to be found in the erratic Rousseau, who represented the spirit of his age,—fantastic, unstable and irresponsible. The French Revolution had not yet come to clear the air of Europe and conditions were most unfavorable for the development of scientific medicine or surgery.

The expression of this spirit of the time was made evident by the substitution for orderly inductive reasoning of fantastic medical treatises by such men as Bishop Berkeley the philosopher, and John Wesley the founder of Methodism, and by an outbreak of quackery probably unparalleled in history.

Berkeley wrote, with regard to tar water, that it "would mitigate and even prevent the smallpox and erysipelas, that nothing is so useful as this

*Presented at the meeting of the Harvard Medical Historical Club on Tuesday, March 2, 1915.

in cases of painful ulcers of the bowels, in consumptive coughs and ulcers of the lungs with expectoration of pus, that it cures asthma, dropsy, and indigestion, and the Kings' evil, all kinds of sores and the foulest disorders," and John Wesley wrote a volume on domestic medicine called "Primitive Physic," which went through 32 editions, a sufficient evidence of popularity. To show the stage of the art represented in this work one or two remedies may be mentioned: "For pleurisy take half a drachm of soot," warm cow dung spread on leather with cummin is advised for "windy rupture," "rubbing with fasting spittle" is recommended for shrunken sinews, etc.

Quackery was rampant and was always the object of Mr. Pott's invincible hatred and continued attack. If there could be a more gullible public than that in America today, which swallows osteopathy, Christian Science, cancer cures and the like, it existed in England in the time in which Mr. Pott lived.

It must be remembered that quackery can boast of a very considerable antiquity and was a curse in ancient Rome. Galen compared the doctors in Rome to robbers, the only difference being, as he said, that the robbers practised their art in the hills, while the doctors robbed in the city. One Thessalus, who styled himself "the conqueror of doctors," walked through the streets accompanied by a crowd as large as that attracted by the mountebanks of the day.

But in the 18th century in England there blossomed out a group of clever rascals, both male and female, who obtained not only popular but royal support, and Queen Anne was a special offender, for being troubled with weak eyes, and evidently being fond of novelty and change, she passed from the hands of one quack to another. One of these, Wm. Read, is an example of the status of the fashionable quack of the day. An unsuccessful tailor, he set up in the Strand as a practitioner and at first pursued general practice, advertising that he could cure cancers, wens, hare lip, wry neck and deafness. Later, specializing in the eye, he hired a Grub street poet to write a poem to him, and an extract from the poem may be of interest.

Whilst British sovereign scales such worth has weighed,
And Anne herself her smiling favors paid,
That sacred hand does your fair chaplet twist.
Great Read, her own entitled oculist,
With this fair mark of honor, sir, assume
No common trophies from this shining plume.
Her favors by desert are only shared;
Her smiles are not her gift but her reward.
Thus in your fair plumes of honor drest
To hail the royal foundress of the feast,
When the great Anne's warm smiles this favorite
raise,

"Tis not a royal grace she gives but pays.

So great was his favor that he was knighted and subsequently became oculist to George the First.

But that there were other points of view with

regard to Read is shown by a stanza from another poem of the period.

Her majesty sure was in a surprise
Or else was very short sighted,
When a tinker was sworn to look after her eyes,
And the mountebank Read was knighted.

The quacks seem to have favored ophthalmology, for the Chevalier Taylor went about dressed in black with long flowing hair and was so facile in a curious inverted manner of speech in which he delivered his addresses that he was esteemed a man of learning, and numbered Gibbon and Handel among his patients, but Dr. Johnson was not deceived by him, but thought him the most ignorant man he ever knew, but sprightly, he added.

This fellow was asked to lecture in the University of Oxford, which is a comment on the standards of the time, and spoke in part as follows:—

"The eye, most illustrious sons of the Muses, most-learned Oxonians, whose fame I have heard celebrated in all parts of the globe—the eye, that most amazing, that stupendous, that comprehending, that incomprehensible, that miraculous organ, the eye is the Proteus of the passions, the herald of the mind, the interpreter of the heart and the window of the soul. The eye has dominion over all things. The world was made for the eye and the eye for the world. My subject is light, most illustrious sons of literature—most intellectual. Ah, my philosophical, metaphysical, my classical, mathematical, mechanical, my theological, my critical audience, my subject is the eye. You are the eye of England—England has two eyes, Oxford and Cambridge, etc., etc."

Proprietary medicines flourished, including Ching's worm powders, John Hooper's female pills, and Della Lena's powder of Mars. The curing of disease by touch was revised by a Mr. and Mrs. Louthenbourg, who acquired an enormous following, while another quack travelled in a coach drawn by six horses, the van being filled by black cats and surrounded by gorgeously appareled outriders.

But if the quack affected striking clothes and methods which would not now be considered in good taste, even for quacks, we must remember that in dress the fashionable English doctor of the day was not, from our point of view, quietly appareled. He wore a powdered wig, a coat of red satin or brocade, short breeches and buckled shoes, and carried a gold-headed cane; on occasions of ceremony he might vary the color of his coat and appear, as in one instance, in violet velvet.

The object of Mr. Pott's especial hatred in this group of historical fakirs was one Mrs. Mapp, a bonesetter. She was the daughter of a bonesetter, but quarreled with her father, and wandered over the country, being popularly known as "crazy Sally." She married at Epson, but she and Mr. Mapp were not altogether

congenial, and after thrashing her several times during the honeymoon, at the end of two weeks he appropriated her savings and left her. A short but eventful matrimonial career being thus ended, she turned again to her profession and established a tremendous following. She lived at Epsom but drove once each week to London in a coach and four with servants wearing gorgeous liveries. When she went to the theatre, so great was her fame that the house would be crowded. Opinions as to her merits naturally differed, but Sir Hans Sloane, who had seen her manipulations, was so impressed that he confided to her charge his niece "whose back had been broke nine years and stuck out two inches." Mr. Pott, on the other hand, wrote of her as follows:—

"We all remember that even the absurdities and impracticability of her own promises and engagements were by no means equal to the expectations and credulity of those who ran after her; that is of all ranks and degrees of people, from the lowest laborer or mechanic up to those of the most exalted rank and station, several of whom not only did not hesitate to believe implicitly the most extravagant assertions of an ignorant, illiterate, drunken female savage, but even solicited her company; at last seemed to enjoy her society."

But apparently the most facile impostor of all was one Mrs. Joanna Stevens, who devised a remedy for stone which was purchased for the public good by parliament, and proved to be a mixture of egg shells, garden 'snails, swines' cresses, soap, burdock, and other innocuous vegetable ingredients. Before its purchase by parliament she had offered to sell the recipe for \$25,000, but a popular subscription failed to reach this amount although much money was raised.

Into this arena was born in 1714 Percival Pott, the son of a scrivener. The father was a man of small means and lived where is now the bank of England. His father soon died, leaving a fortune so small that Pott's share amounted to less than £5, which was found among the surgeon's effects after his death, wrapped up by itself and labelled as his share of his father's estate, which he had kept intact for some seventy years.

His early career was commonplace, a relative of his mother, the Bishop of Rochester, charged himself with his education and he was sent to a small classical school in the hope that he would enter the church. But he decided on medicine, and at the age of 16 was apprenticed to Mr. Nourse, surgeon at St. Bartholomew's Hospital, who lectured in those days on anatomy, not at the hospital but at a house in Aldersgate street, and to Pott fell the duty of acting as Nourse's prosector. From the classical school he acquired a knowledge of the classics which lasted him all his life, and from his dissection resulted an accurate knowledge of anatomy which was of

great use to him. At the age of 22, having paid £254 for his apprenticeship, he took rather an expensive house and started out for himself as a London practitioner.

But he must even then have been a person of some importance, for in the very year in which he started out for himself he was due on a certain date to be examined for his diploma in the Barbers and Surgeons' Company, for the barbers and surgeons, it must be remembered, were not separated for some years to come. The examiners were assembled, but Mr. Pott had not fulfilled the formality of calling on all the examiners to invite them to his examination, but presented as an excuse for not doing so that he had been sent for out of town to attend Sir Robert Goodsall's lady and had not been able to return in time. It was then "resolved that the court would proceed to the examination of the said Mr. Pott notwithstanding his default in attending the examiners, but this is not to be a precedent in time to come to any other person."

From the time that Mr. Pott took this venturesome step in establishing himself in Fenchurch street he went steadily forward, and as his fortunes prospered he moved once or twice, and finally found himself in Lincoln's Inn Fields. He possessed the largest practice of his time in London and his advice was sought by the great and the fashionable, and he was in much demand as a consultant and people came to him from distant lands. The charge was made against him that his great success made him indifferent to the needs of the poor, but his friends claimed that the charge was unjust.

He received professional recognition first by being appointed assistant surgeon to St. Bartholomew's Hospital and later surgeon, a post which he resigned in 1787, a year before his death, having served the hospital as he said "man and boy nearly half a century." He was made a Fellow of the Royal Society in 1764 and in 1786 he received an honorary diploma from the Royal College of Surgeons of Ireland. He was made governor of the College of Surgeons of England in 1765, after it separated from the barbers. He died in 1788 from exposure during a long ride into the country to visit a patient and was buried in Aldermary church in Bow Lane in London.

Mr. Pott lived in stirring times, in addition to being a time when a renaissance was beginning in surgery. He was born in the year when George the First ascended the throne, and he saw the reigns of three Georges. Walpole and the two Pitts were the premiers of his time and he saw the beginning and the end of the American War of the Revolution. The South Sea bubble and the rise of Methodism through the leadership of John Wesley, whose life was contemporaneous with his, left their mark on the life of England. In 1765 Watt invented the steam engine and Adam Smith's "Wealth of Nations" was published, which must be reckoned

as one of the epoch-making books. Living as he did in London and being the important person that he was these results must have influenced his life, for he must have been necessarily in touch with the leaders of men in political and intellectual life. But he never sought political preferment, but quietly kept his path, teaching, writing, operating, healing the sick, always striving for simplicity, for gentle methods and for straight thinking. He was one of the pioneers of modern surgery, and one would search in vain among the list of his English predecessors to find really great names in surgery, but succeeding him, from among those whom he taught, began a new school. His most eminent pupil was John Hunter, shortly after whom came Abernathy, the beginners of a brilliant succession of English surgeons.

In person Mr. Pott was of less than middle stature, but elegant in dress and graceful in deportment. His pictures suggest some facial resemblance to Dr. Samuel Johnson. In conversation he was witty and interesting and possessed an abundant fund of anecdote, both ancient and modern, and his classical knowledge was extensive. He was essentially domestic in his tastes and was happiest surrounded by his large family, having four sons and four daughters, one of the latter becoming the wife of Sir James Earle, a celebrated surgeon who became Mr. Pott's biographer.

But Mr. Pott, brilliant as a surgeon, successful as a teacher, cultivated and popular as a man of the world, really owes his fame to his writings. Up to 1756 he had written but one unimportant paper, but in January of that year, while riding in Southwark, he was thrown from his horse and sustained a compound fracture of his leg of the variety since then known by his name of Pott's fracture, and described by him in his treatise on fractures and dislocations. Conscious of the dangers of a compound fracture he assumed temporarily the direction of his own case, and lying still on the cold pavement would not allow himself to be moved until he had sent to Westminster for two chairmen, who came bringing with them their poles. Still lying on the pavement he negotiated the purchase of a door, which was then nailed to the poles, and on this improvised litter he was transported a long distance to his own house, then near St. Paul's cathedral. At a consultation of surgeons held immediately after his arrival, amputation of the leg was decided on and the instruments were being laid out when his old preceptor, Mr. Nourse, arrived, having been detained so that he was not present at the consultation. He differed from his colleagues and believed that the leg could be saved. After some discussion this view was accepted by the others, and it proved that he was right, for the wound healed practically by first intention.

During the enforced idleness of his convalescence Mr. Pott turned to authorship, and al-

though he was then forty-three, there then began the most useful period of his long career. As his biographer says, "It is by no means impossible that without some powerful check to the train of his pursuits, he might never have discovered in himself those superior powers of scientific disquisition, that correct taste and masterly command of language which have placed him in the front rank of medical writers."

He first wrote of congenital hernia, a subject then but little understood, which involved him in a controversy as to priority with Wm. Hunter. But Wm. Hunter was a fire eater who thrived on controversy, and the matter soon dropped. Then followed in more or less rapid succession treatises, the most important of which were on head injuries, hydrocele, fistula in ano, fractures and dislocations, and finally his epoch-making essays on the disease which still bears his name—Pott's disease of the spine. Originally publishing this in 1779, he amplified it in 1783, and it remains the last of his literary works as well as the one on which his fame largely rests, and deservedly so for he threw light into a dark corner by taking out of the subject of "spinal curvature," so called at that time those cases of posterior curvature of the spine due to destructive disease of the vertebrae, now recognized as tuberculosis, which up to this time had been confused with lateral curvature due to wholly different causes.

The knowledge of spinal curvature up to Pott's time had remained practically what it was in the time of Hippocrates who had advised for the treatment of these cases of posterior spinal curvature that the patient should be tied by the legs to the upper round of a ladder, and while hanging head down the ladder should be dropped from a height, striking with its lower end on the ground, thus straightening the patient's spine. As a further refinement of the treatment, he suggested, "It is also safe for a person to sit on the hump while extension is being made, and raising himself to let himself fall down again upon the patient."

When we come to Ambroise Paré, born in 1510, we find him where we left Hippocrates 2000 years before. I quote from his writings: "A dislocated vertebra standing forth and making a bunch is termed in Greek kyphosis, but when it is depressed it is called lordosis, but when the same is luxated to the right or left side it maketh a scoliosis, which, wresting the spine, draws it into the similitude of the letter S. . . Fluid and soft bodies, such as children, are very subject to generate this internal cause of defluxion. Thus nurses, while they too straitly lace the breasts and sides of girls so to make them slender, cause the breast bone to cast itself in forward or back or else the one shoulder to be bigger or fuller, the other more spare or lean. The same error is committed if they lay children frequently and long upon their sides, then upon their backs, or

if in taking them up when they walk they take them only by the feet or legs and never put their other hand in their backs, never so much as thinking that children grow most toward their heads."

Although the treatment became more gentle, the knowledge of pathology and causation remained about the same as that of Paré until Pott took up the matter, and with his clear insight established the affection as an entity although his attention was first attracted more to the paralysis resulting from the curvature than to the curvature itself. The title of his article was "Remarks on that kind of palsy of the lower limbs which is frequently found to accompany a curvature of the spine and is supposed to be caused by it, together with a method of cure."

How great an achievement this was when one considers the tendency of his age may be best appreciated by a short extract from his work which will show how accurate was his description of the condition:—

"The disease of which I mean to speak is generally called a palsy, as it consists in a total or partial abolition of the power of using, and sometimes of even moving the lower limbs, in consequence, as is generally supposed, of a curvature of some part of the spine.

"To this distemper both sexes, and all ages, are equally liable. If the patient be an infant, it becomes an object of constant, though unavailing, distress to its parents; if an adult, he is rendered perfectly helpless to himself, and useless to others, which, of all possible states, is surely the very worst. . .

"When it affects a child who is old enough to have already walked, and who has been able to walk, the loss of the use of his legs is gradual, though in general not very slow. He at first complains of being very soon tired, is languid, listless, and unwilling to move much, or at all briskly; in no great length of time after this he may be observed frequently to trip, and stumble, although there be no impediment in his way. . .

"Until the curvature of the spine has been discovered, it generally passes for a nervous complaint; but when the state of the backbone has been adverted to, recourse is almost always had to some previous violence to account for it, some pulling, lifting, carrying, or drawing a heavy body, which is supposed to have hurt the back. . .

"The curvature of the spine, which is supposed to be the cause of this complaint, varies in situation, extent, and degree, being either in the neck or back, and sometimes, though very seldom, in the upper part of the loins; sometimes comprehending two vertebrae only, sometimes three, or more, by which the extent of the curve becomes necessarily more or less; but whatever may be the number of vertebrae concerned, or whatever may be the degree or extent of the curvature, the lower limbs only feel the effect—

at least I have never once seen the arms affected by it. . .

"While the curvature of the spine remains undiscovered or unattended to, the case is generally supposed to be nervous, and medicines so called are most frequently prescribed, together with warm liniments, embrocations, and blisters, to the parts affected; and when the true cause is known, recourse is always had to steel stays, the swing, the screw chair, and other pieces of machinery, in order to restore the spine to its true and natural figure; but all, as far as I have observed, to no real or permanent good purpose; the patient becomes unhealthy, and, languishing for some time under a variety of complaints, dies in an exhausted, emaciated state; or, which is still worse, drags on a miserable existence, confined to a great chair, or bed, totally deprived of the power of locomotion, and useless both to himself and others. . .

"The remedy for this most dreadful disease consists merely in procuring a large discharge of matter, by suppuration, from underneath the membrana adiposa on each side of the curvature, and in maintaining such discharge until the patient shall have perfectly recovered the use of his legs. To accomplish this purpose, I have made use of different means, such as setons, issues made by incision, and issues made by caustic; and although there be no very material difference, I do, upon the whole, prefer the last. A seton is a painful and a nasty thing; besides which, it frequently wears through the skin before the end for which it was made can be accomplished; issues made by incision, if they be large enough for the intended purpose, are apt to become inflamed, and to be very troublesome before they come to suppuration; but openings made by caustic are not in general liable to any of these inconveniences, at least not so frequently, nor in the same degree; they are neither so troublesome to make or to maintain. I make the eschars on each side the curve, taking care to leave a sufficient portion of skin between them; in a few days, when the eschar begins to loosen and separate, I cut out all the middle, and put into each a large kidney bean. When the bottoms of the sores are become clean by suppuration, I sprinkle, every third or fourth day, a small quantity of finely powdered cantharides on them, by which the sores are prevented from contracting, the discharge increased, and possibly other benefit obtained. The issues I keep open until the cure is complete; that is, until the patient recovers perfectly the use of his legs, or even for some time longer. . .

"In the preceding tract I have related the appearances which the parts constituting the seat of the distemper make upon examination after death; or, to speak more properly, the different states of these parts in different persons, and at different periods of this disease. These, though necessarily subject to considerable variety, may, I think, be reduced to three general ones.

"1. A small degree of an increase of size in the bodies of the vertebrae, forming the curve, with an apparent laxity in their texture, and a relaxed state of the connecting ligaments, by which they seem to have lost part of their power of holding the bones together.

"2. A more considerable and more apparent enlargement of the same parts of the vertebrae, whose spongy texture becomes more visibly spread through their whole substance, and tending towards a caries, with an apparently distempered state, both of the ligaments and of the intervening cartilages.

"3. A truly carious state of the bodies of the bones; a dissolution or destruction of the cartilaginous substance between them; and a lodgement of sanies on the surface of the membrane enveloping the spinal marrow.

"These are, I think, the most particularly different states or stages of the disorder, and are such as, in my opinion, decisively mark the true nature of it.

In the second paper, published four years later, Mr. Pott simply elaborates his theme and gives more instances of cure.

I was at first at a loss to explain why this treatment should appear to so accurate an observer as Mr. Pott to cure the palsy, because with our more extensive knowledge of the pathology one would not expect any benefit from its use, but I found that it was the practice of Mr. Pott to keep these cases in bed during the treatment by setons, etc., and today we are coming to recognize that recumbency is, after all, one of the essentials for the thoroughly successful treatment of this disease.

I cannot close what I have to say better than by quoting the epitaph of Mr. Pott engraved on a marble slab above his tomb in Aldemary Church, Bow Lane, which was written by his son, archdeacon of St. Albans:—

In Memory

OF PERCIVAL POTT, ESQ., F.R.S.

Surgeon of St. Bartholomew's Hospital during
Forty-two Years, Who departed this Life
December 22d, 1788, aged 75.

He was singularly eminent in his Profession, to which he added many new Resources, and which he illustrated with matchless Writings. Let Posterity revolve the Sum of his Experience, that the World may still enjoy the Benefit of his Successful Practice. He honoured the collective Wisdom of past Ages; the Labours of the Ancients were familiar to him; he scorned to teach a Science of which he had not traced the growth; he rose, therefore, from the Form to the Chair. Learn, Reader, that the painful Scholar can alone become the Faithful Teacher. But his Studies had a double Issue; whilst he gathered the Knowledge of his Predecessors, he perceived their Errors, and corrected them; he discovered their Defects, and supplied them. Original in

Genius, prompt in Judgment, rapid in Decision, he directed Knowledge to its proper Ends; but pursued them when the Aids of Information were exhausted; the last Steps, therefore, and great Improvements, were his own.

His Integrity is before his Judge; Without it, his Skill might have profited Mankind, but could have claimed no Record within these Walls. His private Virtues, his signal Tenderness to his Family, completed an Example, Amiable, Useful, Great.

LATE RESULTS OF SURGICAL TREATMENTS FOR FLEXED SCAPULAE, WITH A DISCUSSION OF THE SUBJECT.

BY HERMAN W. MARSHALL, M.D., BOSTON.

[From the Orthopedic Department of the Massachusetts General Hospital.]

ANATOMICAL variations of scapulae are very common, as is well known, and extreme degrees of these peculiarities not infrequently possess pathological significance. These circumstances led Goldthwait to devise the operation of removing the tips of the superior angles, and he has proved that painful symptoms in backs may be stopped if offending exostoses or abnormally flexed upper parts which scrape over the ribs are trimmed sufficiently to prevent further friction and irritation. This operation has been performed by orthopedic surgeons at the Massachusetts General Hospital upon eleven patients in the orthopedic ward during the four years ending Jan. 1, 1912. All of these patients, therefore, have had three or more years elapse since their operations, and they will be reported individually and collectively in this paper.

GENERAL IMPRESSIONS SUGGESTED BY THE GROUP.

This short series shows that surgical treatments afford very great relief in suitable instances, also dangers of the operation itself under good conditions are clearly indicated. The worst that has happened to any patient has been comparatively trifling sepsis in one case from catgut sutures, and this trouble subsided entirely within a short time. Generally very little discomfort has been noticed by patients immediately following their surgical treatment, and in ten or twelve days they have had enough use of the arms usually to permit return again to their homes. The most satisfactory late results indicate that two or three months ought to be reckoned as a minimum amount of time that will be required for annoying symptoms of soreness after very active use to subside; and some of the best cases have needed a year's time for perfect recovery of normal shoulder functions.

From observing best possibilities of operations and from remembering very favorable terminations of some non-operative cases all patients can be grouped into three classes.

First, those who should receive prompt surgical care.

Secondly, those who should delay having operative interference.

Thirdly, a border-line class.

Regarding the third group there will be always a variety of opinions on account of the diversity of views held by different medical men. The writer submits therefore his own interpretations.

The title of the paper indicates that anatomical defects are being dealt with, yet it is well to remember, whether spoken of or not, that physiological peculiarities also always coexist and enter into every situation, however sharply attention may be focused on structural variations and however striking the latter may be. Some of the cases reported show there were abnormal scrapings of the shoulder blades over the chest muscles, and that these palpable rubbings were stopped by removal of the tips of superior angles of the scapulae yet sometimes without subsidence of painful symptoms. Clipping the bones did not alter individuals' constitutions, and delicate healths with occasional exacerbations of pains continued because the blood continued to be rather poor and variable. Accordingly it seems that the ever present factors, the quantitative composition and variations in the blood from time to time must be thought of always with equal care together with purely mechanical and anatomical causes.

1. The operative group which has been mentioned should include, the writer thinks, those patients of adult age, especially of middle life, who present the following features. Painful symptoms of several years duration that have been associated with otherwise fairly good health. In connection with these limitations there should be localized tenderness combined also with abnormal crepitus at the shoulder blades.

Extremely acute cases of much shorter duration should be included in the first group. (Case 3 of this series.) An artificial dividing line can be suggested as a minimum limit for operative interference, namely, all cases of moderate severity in adults who have shown local signs and pathological symptoms continuously for six months, or milder cases of one year's continuous duration.

2. The non-operative group comprises adult cases of moderate severity that have received no treatment, or those patients that have been treated unsatisfactorily for less than one month with protective and medicinal measures. In mild cases several months must elapse before they should be considered as having passed on from the second class into the third debatable group, from which they finally may emerge at the end of the

year into the first mentioned operative group. Youthful patients with mild symptoms remain in the second non-operative class until they have grown up.

3. The last more doubtful group contains moderately severe types of one to six months' duration; mild cases from several months to one year's duration; and the class of neurasthenic debilitated patients who present signs or symptoms of pathological scapula irritation. Further discussion will be more profitable as special points are taken up in connection with individual cases, and attention will be turned next to consideration of pathological symptoms and signs in their relation to anatomic differences.

Certain patients show very good results who did not exhibit at their operations exceptionally great anatomical peculiarities, so that it seems as though long durations of their irritations were of more importance than over-developed and abnormal flexions of their shoulder blades. However, this is not denying that anatomic variations occur, for Goldthwait* has clearly demonstrated this fact, nor should the greater irritation be doubted of sharply flexed scraping tips of bone in contrast to the even pressures of broad smooth surfaces. Simply it seems that some cases without great structural peculiarities find parallels in certain inflammations of other parts of the body. Knee joints, for example, not infrequently develop insidious synovial inflammations, and then normal functions of normal bones become too irritating. Normal functions are sufficient under such circumstances to keep up chronic pathological conditions indefinitely until obscure vascular defects which have been acting are corrected, and mechanical protection also is simultaneously afforded.

In contrast with patients possessing scapulae of average development with pathological symptoms, it should be recalled that many healthy persons are carrying around flexed and over-developed scapulae without any abnormal indications of these variations, just as variations in other bony structures, anomalies of the vertebral column for illustration very often occur without symptoms or signs. All such individuals, however, have their health constantly menaced to greater or less degree corresponding to degrees of anatomical variation; yet they are enabled to maintain their normal healthy activities because of high degrees of resistance of the tissues and on account of compensating powers of related parts.

It is not of rare occurrence to find slight *scapular crepitus* without symptoms in muscular well-developed men, and it seems that too much importance should not be attached to mere smooth rubbing of the shoulder blades over the irregularities of the chest wall. When combined with tenderness localized at the prominent edges of the scapulae, friction possesses then much

* Goldthwait, Painter, and Osmond: *Diseases of the Bones and Joints*.

more significance. (Case 1 of this series is an illustration of a person who had crepitus before operation and none afterwards, yet who continues to have pains in the shoulder and arm.)

Tenderness in shoulder blades generally means local inflammation; and in routine examination of many back cases in any large orthopedic clinic there are numerous examples discovered of slight tenderness without crepitus among scapulae of debilitated persons. If these individuals do not receive protection and personal hygienic treatment they are liable to develop chronic irritations with the gradual appearance of abnormal frictions of the blades against the chest. Perhaps it will be readily understood that when patients come for the first time with well-developed signs and symptoms it is often difficult to say whether anatomical peculiarities or vascular defects are primary origins; yet, whichever were at fault, surgical interference depends more on the severity and duration of symptoms than on underlying causes. The surgical problem simply is one of removal of irritating bony angles regardless of the manner they acquired their irritating peculiarities, and more or less irrespective of whether they are excessively or slightly developed.

Pain, as shown in this series, is referred by patients to the scapulae, to the region between them, and around to the sternum in front of the chest in acute cases. It radiates up behind the ears at times and also down the arms, and there may be crampy sensations in the trapezius muscle as the latter tries involuntarily to hold the shoulder in comfortable position. Pain is noticed upon motion, especially when the arms are moved in directions that demand greatest rotation of the blades, as Goldthwait has called especial attention to. Shrugging the shoulders, with arms hanging passively at the sides, will produce painful symptoms due to scraping of abnormal scapulae. The pains of subdeltoid bursitis, inflammation of the shoulder joint itself, injuries of the acromio-clavicular joint, neuritis, and myalgias have to be differentiated; but in combination with local tenderness and scapula crepitus there is usually little difficulty in determining scapula lesions.

Sex.—Four of the eleven cases are men and seven are women.

Posture.—All exhibit greater or less degrees of round shoulders, and they help to confirm Goldthwait's idea of an origin in habitual bad posture of the shoulders during the early years when the bones are readily moulded into various degrees of flexion. As the bones strengthen and harden in adult life they retain afterwards their peculiarities permanently, and can be changed only by operation.

Age.—At the time of surgical interference the eleven patients of this series ranged from fifteen years to forty-two years of age, averaging twenty-seven. The girl of fifteen still has pain in her arm, while the man of forty-two at the

other extreme has perfect function of his shoulders. It seems that the best results of operation are seen in middle life, when several years' duration of symptoms have made the advantages of surgery undeniable, and while the individuals are still in active robust health.

INDIVIDUAL CASES.

CASE 1. C. G. Slightly built, nervous girl of 15 years of age. Pain in right shoulder noticed intermittently for many years. Symptoms of burning sensations at night and after using the arm. Pain referred especially to supraspinatus region of the scapula, also at times down the entire arm to the finger tips. Frequent feeling of a lump in the muscles, although no tumor ever has been found upon examination. Treated before operation in the out-patient department of the Massachusetts General Hospital, with local protection obtained by immobilizing the shoulder with adhesive straps, and with a shoulder brace to hold the scapula in the position of greatest comfort. These measures, also exercise and massage, failed to relieve the pain. Examination before operation showed a fairly good standing posture but with slight scoliosis. The right scapula was a trifle more prominent than the left one and tenderness was localized along the vertebral border near the superior angle. Very distinct crepitus could be felt while the arm was being fully elevated, and this scraping had been noticed by the patient herself.

On Nov. 1, 1911, the tip of the superior angle was removed and the patient was discharged from the hospital in ten days. The operation wound healed perfectly without adhesions, although buried catgut sutures caused a little trouble during the first few months afterwards.

Three years and two months after the hospital treatment the patient returned for observation. She complained then of the same burning sensation in the back and arm, and there was the same feeling of a lump, at times, over the shoulder blade. Examination at this time showed a perfectly healed operation scar, arm motions were not restricted at all, no tenderness was observable along the edge of the scapula, and there was no crepitus whatever on movement. The affected shoulder and arm appeared just a little smaller than the opposite one, and the patient explained that this arm tired rather easily. She still appeared delicate, weighed 110 lbs. and had a recent history of tonsillitis and acute articular rheumatism. Upon questioning, the patient would not make up her mind whether or not she thought the operation had been a benefit.

DISCUSSION OF CASE I.

The persistent burning sensations and pain which were complained of at last examination probably would have been noticed regardless of operative interference, for nothing was done surgically that can be held responsible for the continuance of symptoms; on the contrary, marked crepitus and evidences of local inflammation were removed completely. It is impossible to say positively whether these latter definite abnormal signs, local tenderness and crepitus, would have subsided entirely or not without surgical treatment. One possible view

is that the operation did no good although it did no harm beyond submitting the patient to the accompanying inconvenience. Another opinion, equally well justified, is that future trouble probably was avoided, that no harm was done, that a perfectly definite defect was removed which would have become an increasing menace, and that the results have justified the treatment.

CASE 2. Well developed woman of thirty-nine years. She had suffered for fifteen or more years with pain between the shoulders and was unable to hold her arms long above her head. The arms became so "lifeless and tired" that she was obliged always to let them drop at the sides very soon. Examination previous to operation revealed marked tenderness at the superior angles of both scapulae, and the examining fingers could distinguish that the upper parts of the shoulder blades were abnormally prominent. Both scapulae were trimmed in February, 1911, and the patient made an uneventful recovery. Some relief was noticed almost immediately, but tenderness and occasional pains continued troublesome between the shoulders for nearly a year. After surgical treatment the shoulders at first were partially immobilized with adhesive straps, then regular exercises were tried without appreciable benefit being noticed; high frequency electrical treatments next were experimented with, and repeated applications of radiant heat seemed to the patient finally to improve the symptoms gradually.

When last seen three years and ten months following surgical treatment the patient stated that she could then use both arms almost perfectly, being able to hold them above her head without discomfort. She noticed only that the right arm still became rather tired from long use, and at such times pain also would return in it and in the back. At this last examination both operation scars were perfectly healed, slight tenderness to strong pressure persisted over the upper vertebral part of the right scapula but none was present over the left scapula. No crepitus was felt, and all arm motions were made easily in a normal manner. The patient declared that the operation had done her a great deal of good, and that she then was very much better than she had been for many years.

DISCUSSION OF CASE II.

The good results were due it seems almost wholly to removal of the obvious abnormalities at the superior angles of the two shoulder blades; and the slow, nearly complete, recovery in a year's time, after such long duration of symptoms previously is the most interesting feature of the case.

CASE 3. M. C. Muscular man of forty-two years, who had knife-like pains in his shoulder blades extending around at the same level to the sternal region in front. Symptoms were noticed when carrying heavy quarters of beef upon the shoulder. Continuance of this work aggravated the first mild ache until it became unbearably severe after four months. He had suffered no single severe trauma or recent infection.

Before the operation soft crepitus could be felt on moving each scapula, and the upper vertebral border

of the left one was tender to pressure. Moderate incurving of both tips was found at operation in December, 1908, and pieces of bone one-half an inch across were removed from them. In ten days the patient could use his arms comfortably, the operation wound had perfectly healed, and he was discharged relieved.

One year later there was a return of pain between the shoulder blades, and mechanical exercises were advised; but these were not carried on long because the symptoms subsided.

Four years after operation pains in elbow, wrist and shoulder were complained of, and an x-ray showed some hypertrophic changes about the elbow.

At the last visit, five years after surgical treatment, both shoulders were perfectly normal in strength and function. There was no crepitus or tenderness over the scapulae, and the patient continued to work handling heavy beef. He thought his operation had been a very great benefit to him.

DISCUSSION OF CASE III.

Would the very acute symptoms in this case have subsided if the arms and shoulders simply had been treated by immobilization? It seems probable that these pains would have quieted down slowly under protection if the latter were persisted with long enough, but also, on the other hand, perhaps there would have been much more trouble in the two upsets subsequently than was actually experienced with the two scapulae that already had been trimmed.

The worst that can be said in this instance is that surgery theoretically may possibly have been unnecessary, yet this cannot be proved. It is certain that the patient wanted as prompt relief as possible from his severe symptoms, and this was given him in a few days. At the last visit he was greatly pleased and had perfect use of his arms; therefore, taking into account all circumstances, it seems that the operation was indicated and has justified itself.

Predictions as to the future in this case might be hazarded, in view of the two slight recurrences of symptoms, that autointoxications or debilitated states will be likely to cause a return of the shoulder pains; and that prompt regulation of vascular abnormalities may constitute as prominent a feature of future therapeutic procedures if any are needed, as surgery has been in past treatments.

CASE 4. S. W. C. Fairly well developed woman of thirty years. Pain in left shoulder blade for sixteen or seventeen years. Symptoms noticed mainly after using the arms. Painful feelings described as a dull ache, which led to the desire to shift continually the position of the arm. It was impossible for her to get into a comfortable attitude, and after much exercise very severe pains darted up the neck behind the ear and also down the arm. At the examination before operation a distinct click was discovered on moving the scapula, and its superior angle could be felt considerably flexed.

The patient had tried various local applications without benefit during the earlier years of the trouble, and had become resigned to the pain. She

came to the Massachusetts General Hospital complaining of cough and progressive weakness, and the possibility of incipient tuberculosis was investigated. She incidentally mentioned the back pain, and was referred then to the orthopaedic out-patient department, where protection of the shoulder was attempted unsuccessfully for two months before surgical measures were advised.

In March, 1909, the superior angle of the left scapula was cut off, and the patient was discharged from the hospital in nine days with the arm comfortably supported in a Velpeau bandage. The operation wound healed quickly and perfectly. At the end of three months she still complained of some soreness after sweeping and other household duties, but in less than a year all symptoms had entirely gone and they never returned.

The last observation was made five years and ten months after surgical treatment, and at this time there were no local signs of tenderness or crepitus. The patient said the operation had afforded wonderful relief; that it was impossible for her to describe the great improvement which had taken place over the continuous nagging pain which she previously always had endured. She was able when last seen to labor daily in a large Boston department store, doing very active work.

DISCUSSION OF CASE IV.

The hospital records state that at operation the scapula was found decidedly flexed, and, therefore, the late results indicate beyond any reasonable doubt that the improvements observed should be ascribed largely to removal of the faulty part of the bone.

An interesting feature of this case was the preliminary unsuccessful attempt to relieve symptoms by immobilization. The shoulder was held with adhesive straps in a position which seemed correct to the observer, and the most acute pains were prevented by this protection, yet the patient begged to have this treatment stopped after a few days, for the chronically inflamed parts continued to ache incessantly and the feeling of weight and pain became unbearable when the position of the shoulder blade could not be shifted. These symptoms were uncontrollable with salicylates.

Most readers will feel inclined to believe that an operation was clearly the best method of treatment in this instance, although there may have been a theoretical possibility of subduing the irritation by very prolonged tedious non-operative measures with disuse of the arm.

CASE 5. E. W. T. Round-shouldered woman of twenty-seven years. History of pains and dull aches in shoulders for seven years, worse for one year preceding operation. Patient said she had never been very strong as a girl. Examination demonstrated distinct crepitus over each shoulder blade when it was moved over the chest wall, and considerable flexion of both superior angles could be felt. Pain was referred to the scapulae and to the trapezius muscle above in the shoulders and neck. The weight of the clothing bore uncomfortably upon the shoulders, and lying on the back had become exceedingly unpleasant on account of pain it caused.

On May 2, 1910 both scapulae were operated on and the tips of their upper angles cut off. In ten days the patient was allowed to go home, returning to the out-patient department for further care. She was held intermittently for six months afterwards with adhesive strips, then was fitted with a shoulder brace which she possessed at her last visit.

Three months after her surgical experience she became discouraged with indefinite persistent pains in the back of the neck, but at the end of a year most of the symptoms had gone.

At the last visit four years and eight months after her surgical operation she was feeling very well, had gained twenty pounds in weight, could use her arms freely and lie comfortably in any position. She noticed a little soreness yet, however, after vigorous prolonged sweeping, and there was just a little tenderness along the vertebral edge of the left scapula, but no scraping of the bone on motion. No supports were used.

She said that she had discarded the shoulder brace three years ago, except for occasional short periods when soreness returned after too much use of the arms. She was doing her own housework when last seen. Chronic constipation continued to bother her, and tonic eliminative measures,—sodium phosphate, elixir of iron, quinine and strychnine phosphates, and extra water drinking—were suggested for trial periods of three weeks whenever necessary.

She considered her operation a very great benefit and said that it had transformed her from an invalid into an active woman.

CASE 6. J. M. C. Forty-one years of age. Teamster. Patient fell from third story window while drunk five years before operation and landed on his back. He suffered with rheumatism and a dull ache in his shoulders afterwards and had difficulty in raising the arms above the head, also something seemed to catch him in the arms and shoulders when he lifted. Upon examination distinct crepitus was felt under both shoulder blades, and he was promptly advised to have the scapulae surgically examined. The under surface of the superior angles were found roughened, but the deformities of the upper portions were not excessive. Both scapulae were trimmed and smoothed. There was very little post-operative discomfort and the wounds healed perfectly. He returned to the hospital three weeks after his surgical treatment and this was the last time he was seen. Then there was marked relief from the previously observed symptoms.

CASE 7. C. H. C. Twenty-one years of age. Hotel clerk. He had had soreness in the left side for one year which extended down the arm and up along the back of the neck. The symptoms had become severe enough to prevent work when he first came for treatment, and he was immediately referred to the orthopaedic ward for surgical care.

The examination showed localized tenderness with very marked scraping of the left shoulder blade but with none over the right shoulder. The angles of both scapulae were removed. There was very little post-operative discomfort. Numbness in the arm and neck had improved but had not entirely cleared up when he was discharged. He had good motion in the arm and the wound had healed solidly. He never returned nor was heard from after he left the hospital nine days from the time of operation.

CASE 8. M. H. Shoemaker. Examination revealed definite shoulder crepitus in a droop-shouldered Armenian of twenty-one years. He exhibited old scars of wet cupping over shoulder blades and complained of inability to stand erect or to throw shoulders back. For two weeks he had had pain in the left side. Both shoulder blades were trimmed and the wounds healed perfectly in thirteen days. The patient could stand more erect immediately afterwards and there were no abnormal rubbings of the scapulae on the chest wall when he was discharged. He was never heard from after leaving the hospital.

CASE 9. L. L. E. Nineteen year old girl. Twenty-two months before operation she began to complain of pain in the shoulders. Exercises were prescribed for nearly a year, then a plaster jacket was applied for a few months to hold the spine hyperextended, and finally a shoulder brace was fitted seven months before her surgical treatment. None of those measures relieved the pain, therefore it was decided to trim the shoulder blades although there was no crepitus, because the shoulders were obviously drooping and the symptoms had persisted. Both scapulae were trimmed and the operation wounds healed *per primum*. There was very little post-operative discomfort. The patient was discharged from the orthopedic ward in fourteen days, and continued to come to the out-patient department for nearly a year longer. She continued, however, to have pains in the neck and back that very slowly diminished under manipulation and exercises.

She returned six years and a half after her surgical treatment, and at that time had practically no pathological symptoms. No crepitus could be observed, but there was a slight tenderness at one spot on the right scapula. The brace had been discarded for four years. She thought her operation a success.

CASE 10. M. M. Parlor maid. Twenty-two years old. She came for treatment three months before her operation and had had more or less trouble in the shoulder for seven years following an injury. There had been pain in the shoulder blades for several months before admission to hospital. Tenderness and crepitus were found in the right scapula. She was treated for a month or so with strapping before the shoulder was operated on. Her convalescence was uneventful, and she was permitted to leave in fifteen days. For two months she returned to the out-patient department for further strapping and chloroform liniment, and after six years and ten months she was heard from finally. She stated then in a letter that she had completely recovered and was a trained nurse.

CASE 11. E. A. F. Woman of twenty-six years. Back ache, pain in shoulders, and leg pains at times for eight years. Before operation motions of the shoulders were guarded slightly, and scapula crepitus could be felt. The upper angles of the shoulder blades were trimmed at operation and the recovery was uneventful.

A spring steel back brace was recommended after operation. Seven months after surgical treatment there was a little tenderness still over the left scapula, but both of them moved up and down smoothly on the chest wall. She reported by letter three years and five months after her hospital experience that the operation had left no bad effects upon the shoulders, but she had not been able to re-

gain her healthy vigor and that she then was in Florida trying out of door exercise treatment. She had been obliged to give up the back brace on account of the discomfort it produced.

SUMMARY.

Six of the eleven patients operated on returned for observation and two reported by letter. Six of these eight thought they had been much benefited, one could not make up her mind, and one said she could use her arms just the same as before the surgical treatment. The three persons who had not been heard from recently, were all improved when they were seen soon after leaving the hospital. None say they are any worse, and no weakness or other objectionable after-effects that can be ascribed justly to surgery have been discovered in any of them. With regard to time for recovery, acute symptoms in all subsided by the time operation wounds healed enough to permit the patients to leave the hospital; and in three months the large majority had good function in the shoulders again. In a year's time some of the most protracted cases had been perfectly relieved.

Neurasthenic pains in arms in growing or debilitated persons were not relieved by scapula operations.

Non-operative treatments—shoulder braces, medicinal tonics and eliminants, hydrotherapy and exercises—should always be tried first for a month or more whenever circumstances permit. Many mild cases recover without surgery, and the latter should be employed only when subsequent advantages seem to overbalance the slight dangers and inconveniences of the operation itself, and when patients seem to be of suitable type. The most favorable cases are middle-aged persons in otherwise good health, and the most unfavorable combinations are found in young individuals from fourteen to eighteen years, who are nervous and debilitated.

PROGRAM AND DIRECTIONS FOR THE MENTAL EXAMINATION OF ASOCIAL, PSYCHOPATHIC, AND DOUBTFUL SUBJECTS.*

BY ROSE S. HARDWICK, BOSTON.

Instructor in Education, Boston School of Physical Education; formerly Assistant in Psychology, Psychopathic Hospital, Boston.

FOREWORD.

THE writer is one of a group of people who are working on the problem of mental examina-

* Being Contribution of the State Board of Insanity, Number 41 (1915.7). (*Bibliographical Note.*—The previous contribution (1915.6) was by H. C. Solomon and E. S. Welles, entitled "Varieties in the Gold Sol Reaction Type in Different Locs of the Cerebrospinal Fluid System," published in the BOSTON MED. AND SURG. JOUR. April 29, 1915.)

tions at the Boston State Hospital, Psychopathic Department.

To meet the needs of that and similar institutions the Yerkes-Bridges Point Scale was developed and was put into use at the hospital in December, 1913. This, however, was not devised to be an exhaustive examination, but, rather, to serve as a preliminary, giving immediately such data as would be needed in every case, and preparing the way for a more intensive study, which could then be adapted to the requirements of the individual subject.

The writer's special problem is the organizing of these supplementary tests. The program outlined in the following pages is tentative, and is intended to be superseded later by a more complete and satisfactory treatment. Especially in the field of affectivity are the present methods of testing felt to be inadequate.

In this provisional form the program is primarily for the guidance of inexperienced examiners, though the writer hopes that it may be of service to others also.

ABBREVIATIONS.

Most of the tests to be considered are found in one or more of four series, namely, the Yerkes-Bridges Point Scale, the Binet-Simon Scale, the Healy Tests, and the Knox Scale. For convenience of reference the several tests will be denoted by the initial of the author's name followed by the number of the test in his series. Thus, B VII 3 is test number 3 of the 7-year group of the Binet-Simon Scale, and H IX is test number IX of the Healy series.

Knox, in his description of his own scale, uses Arabic numerals for both test and year, but the Binet notation is the clearer, and, therefore, has been adopted for the Knox Scale as well.

References to Whipple's Manual^{10*} are given by test numbers. Thus, W 16 is test number 16 in the Manual.

Throughout this discussion the references to the Point Scale have been made to agree with the revised form of the record sheet.

WORKING REFERENCES.

The examiner should have the following publications at hand for constant reference:

BINET, A., ET SIMON, TH. A method of measuring the development of the intelligence of young children. (Town, C. H., trans., 2d ed.) Chicago Med. Book Co., 1913.

HEALY, W., AND FERNALD, G. M. Tests for practical mental classification. Psychological Monographs, 1911, Vol. 13, whole No. 54.

KNOX, H. A. A scale, based on the work at Ellis Island, for estimating mental defect. *J. Amer. Med. Assoc.*, 1914, 62, 741-747.

WHIPPLE, G. M. Manual of mental and physical tests. Warwick and York, Baltimore, 1910.

This is now being revised and enlarged, but as yet only the first volume of the new edition has been issued (Warwick and York, 1914).

YERKES, R. M., BRIDGES, J. W., AND HARDWICK, R. S. A point scale for measuring mental ability. Warwick and York, Baltimore, 1915.

This is to be ready in the spring. Meantime a preliminary description of the Point Scale has been published as follows:

YERKES, R. M., AND BRIDGES, J. W. The Point Scale: A new method for measuring mental capacity. *Boston Med. and Surg. Jour.*, 1914, 171, 857-866.

* The reference numbers in the text refer to the "references" given at the end of the article.

METHODS OF TESTING.

THE YERKES-BRIDGES POINT SCALE.¹¹

Of the various series of tests now in use at the Psychopathic Department of the Boston State Hospital, this one alone has been developed with special reference to the needs of such an institution. Hence it forms the natural point of departure for the present discussion.

As at present constituted, this scale is especially suited to the work with pre-adolescents. It is, as the name indicates, a point scale and not an age scale. The tests are arranged in order of difficulty. Whether the subject is a child of three or an adult, the examiner begins with the first test, and gives the series entire, or until he is satisfied that the limit of that individual's mental attainment has been reached. In this way all the principal intellectual functions are tested for every subject.

The result of a point scale examination may be expressed in three ways, namely, by the score, the mental age, and the coefficient of mental ability. All three of these expressions should appear on the record sheet.

Suppose, for example, that a subject 12 years old scores 68 points. The examiner writes "68" after the phrase "total credits" at the top of the record blank. The graph shows 68 to be the norm for 11.3 years, and "11.3" is, therefore, recorded after the words "mental age." The same graph shows, also, that the norm for this subject's chronological age is 77 points. His coefficient of mental ability is, then, 68/77, or 88%. This coefficient should be entered on the same line with the score, the norm being written on the line below. For the present the mental age by the Binet Scale should be obtained for purposes of comparison, and it should be written after the Point Scale age. Thus the record for the supposed case would read as follows:—

Mental age, 11.3 years, Y; 9.8 years, B.
Total credits, 68. Coefficient, 0.88.
Norm, 77.

Detailed information as to the giving of the several Point Scale tests, and the interpretation of the results by the aid of norms will be found in the printed instructions, but it may be well to emphasize at this point the importance of the data indicated at the top of the record blank.

The date of the examination and the date of the subject's birth should be recorded exactly, and in the form 1914-10-6, rather than October 6, 1914.

After the words "examined by" the initials of the examiner are sufficient if he is making examinations regularly for a number of months, but if he is making few examinations, or only occasionally, his last name should appear in full.

The name of the subject should be given in full, and always in the same order, thus, Smith, John Henry.

Under "nationality" should be stated, if pos-

sible, the birthplaces of the subject and of his parents, and the race to which they belong, if the birthplace does not sufficiently indicate that. For example, in the case of German Jews, both race and birthplace should be given, since birthplace alone would indicate German stock, and race alone would give no clue to the early environment. It is especially important to make note of the fact if the subject or either of his parents is colored, since neither name, birthplace, nor language necessarily gives any clue to that. The more definitely the place is stated the better. For instance, "Halifax, Nova Scotia" is distinctly better than "Canada." In all doubtful cases the examiner should ascertain if the subject is accustomed to speaking or hearing any other language than English at home, and, if so, that fact should be recorded with the name of the language. The place of birth and the race do not by any means dispose of this question. A Canadian of French extraction may speak either French or English, and a Hebrew of American birth either English or Yiddish. If any language difficulty is present or suspected, that, also, should be stated distinctly. Much of this data can often be transferred directly from the "history" of the case, but this should be done before the close of the first interview in order that the examiner may inquire at once in regard to any missing items. A little experience will make it possible to record the above data with entire clearness and yet compactly. Generally recognized abbreviations should be used wherever possible without ambiguity.

Under "school grade," if the subject is still in school the mere number of the grade is sufficient. If he is not in school, the age as well as the grade at which he left should be given. If he is in a special class, the number of the grade from which he entered it should be stated.

At first this may seem an unnecessary and burdensome amount of detail. That it is not so in reality, however, becomes evident with experience.

When a subject returns, as he does not infrequently, after an interval of months or years, for a second examination, the value of the second examination must depend in no small degree on the fullness and exactness of the record from the first.

Moreover, it is only by the accumulation of such data that our present norms can be used, improved, and new ones established. Thus the facts as to language are necessary if the language norms are to be utilized, while the establishing of racial norms must wait for the gathering of just such data as are called for here. If these facts are not ascertained at the beginning of the examination there is danger that they may not be ascertained at all, or not with sufficient exactness to be useful. An item that could have been recorded in a few seconds at the time of the examination may easily cost someone a

half hour's search at a later date—and may not be forthcoming after all.

In the absence of definite information as to sociological status, it is generally safe to assume that a subject in a state institution belongs to the unfavored group, and to judge him by the corresponding norm.

The examiner is urged to follow strictly the instructions as to recording, if possible, the exact words of the responses for Nos. 7, 9, 10, 14, 15, 17, 18, 19, and 20. In the case of responses difficult to evaluate the advantage of this course is obvious. If the examination is repeated, changes in the type of response may be quite as significant as changes in the score. Finally, as will be seen, these details are essential if the Binet rating is desired.

THE BINET-SIMON SCALE.

A full discussion of the Binet tests, together with a good deal of illustrative material, will be found in Town's translation.¹ This is an authorized translation of the latest Binet revision, and should be followed except for the modifications introduced by Goddard.^{4, 6} His version is especially adapted to use in this country, and it provides a group of tests for eleven years which the 1911 revision by Binet does not. Hence we use the Goddard record sheet, and adhere as closely as possible to his rules. The necessary modifications of the Point Scale and the Binet procedure are given below.

For convenience the Binet tests will be treated here in two groups according as they are, or are not, represented on the Point Scale.

Binet tests represented on the Point Scale.

Y 1 = B VI 5. Goddard says, "Child must give all these comparisons correctly," but note that Binet shows each pair of faces only once. That is, the Binet score depends on the result of the first exposure of each pair, and no error is allowed.

Y 2 = B VII 3. No modification.

Y 3 a = B IV 4. Goddard counts two correct responses out of three a success, hence it may be necessary to give a third trial.

Y 3 b and c = B V I. No modification.

Y 4 = B IV 3, VIII 5, X 3, and XII 1. The Binet procedure allows the subject three trials on each group, and reckons one correct repetition a success. Hence, a third trial may be given when necessary.

Y 5 = B VIII 2. Binet permits one error (omission or inversion), and Goddard advises to "hold pretty strictly to time."

Y 6 = B III 2, V 3, XII 3 (?). In this test, (d) contains 24 syllables, whereas B XII 3 contains 23. Goddard says of the latter: "Sentence too hard—effort is being made to standardize one. In the present sentence credit if it contains no more errors than one omission and one transposition." Y 6 (d) should be counted in place of the Binet sentence and scored as above.

Y 7 = B III 4, VII 2 and XV 1. This is credited by Binet on the basis of the most frequent type of response. Enumeration, description, and interpretation correspond, respectively, to B III 4, VII 2, and XV 1.

Y 8 = B IX 5. As Binet counts two correct arrangements out of three a success, a third trial may be necessary.

Y 9 = B VIII 1. Goddard warns against accepting automatism or expecting *logical* answers. One point of difference for each pair is sufficient, and two correct comparisons count as a success.

Y 10 = B VI 2 and IX 2. "Spoon" and "baby" may be treated as equivalents of "fork" and "mama," respectively, but the fifth word, "table," must be given also since the Binet scores, for both VI 2 (in terms of use) and IX 2 (in terms superior to use), are based on three out of five responses. Goddard warns here against crediting automatisms.

Y 11 = B XII 4. Binet credits a success if the suggestion is resisted for two of the last three pairs of lines.

Y 12 = B V 2 and VII 4. Binet used a pen for these drawings, but Goddard prefers a pencil. Generally, drawings that receive one point credit on the Point Scale would be accepted in the Binet test. Doubtful cases must be settled by comparison with the specimen drawings given by Binet.

Y 13 = B XI 3. Less than sixty words receive no credit in the Binet test. Goddard says, "Do not credit numbers given serially, nor repeated words if they occur too frequently."

Y 14 = B X 5 and XI 2. Goddard permits the examiner to explain the meaning of "sentence," but not to illustrate. He says, "The sentence may lack sense, and yet be acceptable." For X 5 he accepts a compound sentence, but not separate sentences. For XI 2, the sentence must be either simple or complex, compound sentences being refused credit here.

Y 15 = B X 4. This makes use of only four of the eight questions in the Binet test, and enough of the remaining four must be given to allow of reckoning as a success two in the first series and three in the second. Goddard says that the "first question in the second series ought to read, 'What ought one to do if he is afraid he'll be late for school?' The only correct answer is 'hurry' or 'run,' or some expression for hastening. Second in second series ought to read, 'What ought one to do before deciding an important matter?'"

Y 16 = B X 2. Credit of three points on the Point Scale is generally equivalent to success in the Binet test. Binet counts the test as passed "when one of the designs is reproduced exactly, and half of the other is correctly drawn," and Goddard defines "half right by adding, if one component part is missing or two component parts transposed."

Y 17 = B XI 1. Binet requires three of the five responses to be correct.

Y 18 = B XI 5. Binet requires two of the three sentences to be correct, and he accepts only the following solutions:

I asked the (or my) teacher to correct my (or the) paper.

A good dog defends his master bravely, *or*, A dog defends his good master bravely.

We started at an early hour for the country, *or*, At an early hour we started for the country.

Y 19 = B XII 2. Binet credits two correct responses as a success.

Even when the above directions are carefully followed, the results are not in all cases precisely the tests described in Goddard's version of the Binet Scale. The differences are not great, and it is probable that they neutralize each other to some extent. At any rate, the resultant error is almost certainly less than would be entailed by a repetition of the tests.

Binet tests not represented on the Point Scale.

The following are Goddard's modifications of the rules for the several tests:

III 1. "Other parts of the face are harder. Do not persist to the point of annoying the child. If necessary, because of shyness, help on the first and then if he succeeds on the next two give him a fourth one. *Be sure you do not help.*"

IV 1. "Be sure there is real discrimination and not thoughtless repetition of the first or last term."

IV 2. "Other objects than those given, may be used if the examiner is sure child is familiar with them. Say, 'What is this?'"

V 5. "Give the child no suggestion, place the two triangles before him with the long legs facing each other and the hypothenuses turned away from each other."

VI 1. "As in IV 1 and 4, be sure the answer is not accidental. If in doubt, repeat question later."

VI 3. "Give clear directions—then repeat them, and after that give the child no more help. *Be sure the three commissions are not conflicting, ambiguous, or unusual.*"

VIII 3. "Child must not be given one name with which to start. May begin with any one so long as he names all in order."

VIII 4. "Be careful of stamp arrangement—111222. Say, 'You know how much a green stamp costs (illustrating with one stamp) and how much a red stamp costs (illustrating)? How much do all these cost?'"

IX 1. "Real money only must be used and change must be counted out as well as stated (except in cases where the child is obviously be-

yond this test.) Use four cents from twenty (two dimes,) or six cents from twenty-five as an alternative."

IX 4. "Do not name a month to start the child. Child may begin with any one so long as he names them all in order."

X 1. "Our question differs from Binet's, because our currency does not fit. His test involves *coins*, all of which are in use. Our *coins* above fifty cents are rarely seen by children. Therefore we show coins up to fifty-cent piece (but not in order)—these must be named correctly. Then he may name the paper money from memory. If he names 2, 3, 4, 6, 7, etc., dollar bills ask him if he ever saw a 3 and a 4, etc.; if he insists that he *has* seen them the question is given no credit, but if he merely knows there is a higher series and does not insist that he knows *from experience* that there are 3, 4 or 7 dollar bills, we credit him."

XI 4. "Always give an explanation of the meaning of rhymes and an illustration (we use "floor" as an illustration). Do not accept syllables that are not real words, although they may rhyme. Three rhymes with each of the three words are required; one minute is allowed for each series."

XII 5. "If answers are indefinite, query further to be sure whether child has correct idea or not before crediting."

Writing in 1913³, Goddard says: "'Fifteen years' and 'adult' have not proved reliable. One may try them for his own purposes, but there seems no way to score them, therefore we do not include them in the scale." Also, in the earlier article, 1911,⁴ in which he set forth this revision, he says: "We have concluded that adult 1 and 2 test special traits rather than universal, *e.g.* we found in a mixed group of educators and scientists six out of twenty succeeded with No. 1. In another group, psychologists, twelve out of eighteen succeeded." In other words, these two groups are to be treated as supplementary tests, the regular scale ending with twelve years.

In XV 2, Goddard says, "Child must not see a watch or clock. It is a test of imaging power." 11.15 and 4.30 should be accepted (W. page 487).

XV 3 is fully discussed as H XI⁷. It is convenient to lead up to it with H IX and X, a very bad failure on either of these indicating that the test has proceeded far enough. Goddard suggests "war," V J F, for illustrating the use of the code, and gives "Caught a spy" as the test sentence. Since this is not to be used as a part of the Binet Scale, the sentence given by Healy ("Come quickly") should be used, with Goddard's sentence as an alternative when the examiner wishes to give a second trial.

XV 4 should be given according to Healy's instructions (H XV), using the full list of twenty words, and recording the reaction time for each. This necessitates making it an oral

test and using a stop watch.* We accept Goddard's list of alternative responses.

"Besides the obvious answers," he says, "the following are acceptable as right or half right:—

- 2, in or indoors (half);
- 3, lazy or slowly (half);
- 4, little or low (half);
- 5, short (half);
- 6, soft or low (right), whisper (half);
- 9, sorry or sorrow (half);
- 10, right or truth (half);
- 11, dislike, unlike or hate (right);
- 13, healthy (right)
- 14, mad (right);
- 15, broad (half);
- 16, filled (right);
- 18, none (right);
- 19, under (right)."

For the "adult" tests, when given, the Binet procedure is to be followed.

When the Point Scale examination has been completed, the Goddard record blank for the corresponding Binet tests may be filled out from this, placing before the numbers of the several tests, plus signs to indicate successes, and minus signs to indicate failures.

To obtain the Binet rating the examination is continued in the following manner: The examiner looks for the first failure thus far recorded on the Binet sheet. Suppose, for instance, that it occurs at VIII 2. He will then give the remaining tests for seven years, namely, VII 1 and 5. If one or both of these is a failure, he will continue to work backward until an age is reached for which all the tests are passed. He will then reverse the process and work forward, beginning, in the supposed case, with the tests for eight years, until an age is found for which all are failures.

This last, however, is a general rule to which the examiner may safely make certain exceptions after he has acquired a little experience. Thus XII 4 is often passed by individuals otherwise distinctly below the twelve-year level. Hence, if a subject passes on XII 4, but fails on XII 1, 2 and 3 (or the corresponding Point Scale tests), it is generally safe to infer that the limit of correct performance has been reached, and that it would be a waste of time to attempt XII 5, to say nothing of the tests for fifteen years. The same thing is true in less marked degree with reference to XI 3 and XV 1.

The Binet age should be reckoned according to the later Binet rule, namely, starting from the age at which the subject passes all the tests, one fifth of a year is added for every one of the more advanced tests passed (at four years the fraction would be one-fourth).

*The stop-watch known as the "seven jewel lever chronograph" made by the Leonidas Watch Company, Switzerland, has been found satisfactory for examination work. It can be obtained from dealers in this country for about \$7.50.

URETHRAL CARUNCLE.

BY EDWARD L. YOUNG, JR., M.D., BOSTON,

From the Genito-Urinary Service, Massachusetts General Hospital.

THE records of the cases of new growth of the female urethra, going under the name of caruncle, which have been operated on at the Massachusetts General Hospital during the past twenty years, have been studied, and the symptoms, and when possible the pathological findings, classified, in order to verify and emphasize those points of importance which we have all believed to be true and to see if by chance there are other points not now emphasized which should be brought out. This series includes only the cases operated on in the house, as they have the most complete data.

Pathology. There were nineteen cases in which pathological work had been done and in which the slides were available. Dr. William F. Whitney very kindly went over these slides to verify the old reports and to see if he agreed with the general classification. The interesting thing, in fact almost startling thing, about these slides is the number of cases in which the question of malignant degeneration was raised because of the irregularity of epithelial cell growth in crypts and infoldings from the surface and of islands of epithelial cells included in the tissue. In the original reports four cases were called either definitely malignant or with an atypical epithelial growth sufficient to make the pathologist emphasize it. On going over these slides with Dr. Whitney, there was one other which he considered suspicious, though not definitely malignant. This makes five out of nineteen cases, or more than 25%, where the irregularity of cell growth raises the question of carcinomatous degeneration. There were, besides these five cases, three others with very irregularly lined epithelial surfaces. The age of the patients in these cases varied all the way from six to sixty-three years. Three of the five cases I was able to get later data on. Two of the three had no signs or symptoms, one four and one eight years afterward. The third came to the out-patient department in response to a letter. It is now six years after operation. Aside from the fact that she is somewhat run down, she is in good general condition. She has the same symptoms as before operation and examination shows a tumor surrounding the meatus about one-fourth inch in diameter in its thickest point. To the finger the whole length of the urethra feels hard, thickened and indurated. There are no palpable glands anywhere. She refuses further operative interference of any kind, though told of possible danger, for the slide from her earlier caruncle looks definitely malignant. Plates Nos. 1 and 2 give rather poorly high and low power of this.

The papillary form of redundant epithelial growth was also encountered and is illustrated

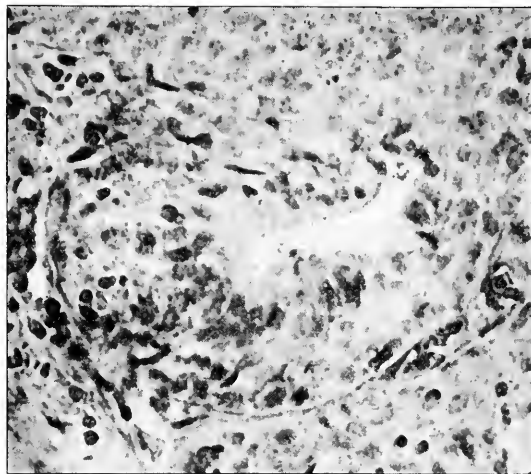

FIG. 1.

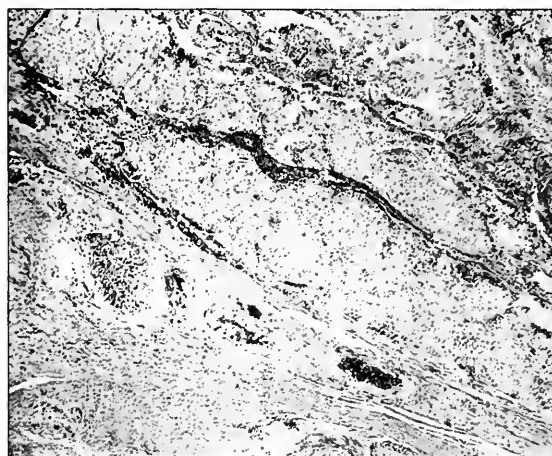

FIG. 2.

by Plate No. 3. This is an unusual type of the tumor.

The remaining cases seem to fall more or less clearly into two groups; in one the main tissue is very vascular and surmounted by a thin layer of epithelium, the angioma type, Plate No. 4. In the other it is typical granulation tissue, the granulomata, Plate No. 5. There is, of course, no hard and fast demarcation, but in general this classification covers all cases.

Symptoms. According to most of the textbooks, burning and frequency of micturition, together with great sensitiveness, are characteristic of this condition. In this series, 26 or 35% of the cases had no symptoms of any kind pointing toward the caruncle. They came for the relief of other conditions, mostly pelvic or perineal, and during the course of the examination the growth, varying in size from a "small tab of mucous membrane" to a strawberry, was discovered and later removed. The causes other than these which were responsible for sending patients to the hospitals were as follows: Twice the family physician discovered the tumor and advised operation, three times the complaint

FIG. 3.

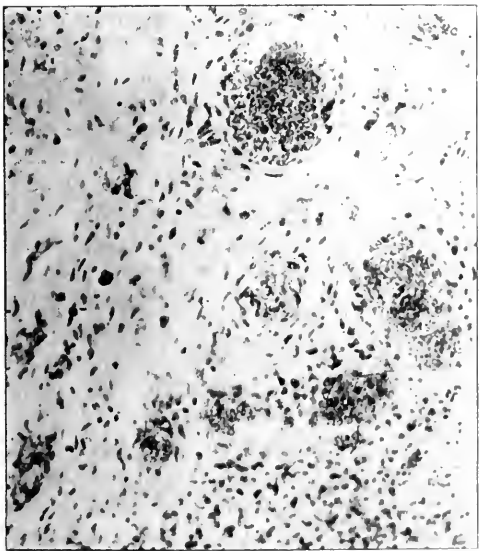

FIG. 4.

the urinary meatus; three of these were made worse on walking or standing, and two made worse and one better on micturition. This made thirty-five, or one half the cases, that had no urinary symptoms.

The half that did have bladder symptoms showed the following variation: fifteen had frequency and burning, thirteen had burning without frequency and five frequency only. Two patients had incontinence without other symptoms, but it is highly improbable whether the

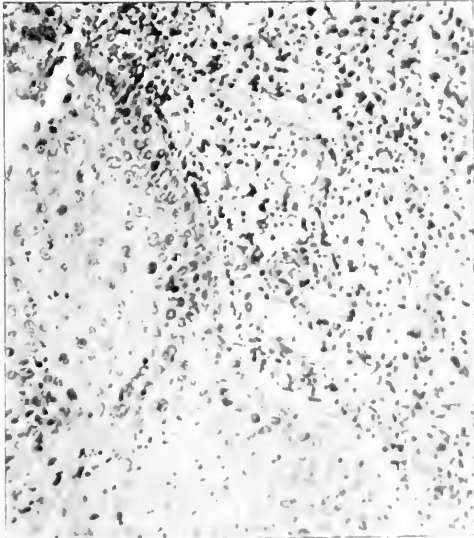

FIG. 5.

was hemorrhoids and once fissure. Twice, in patients aged six and nine, the mothers discovered the tumor and once the patient came to find the cause of painful coitus. Six patients noticed the growth because it had been removed once and they were on the lookout for a recurrence. Aside from these twenty-six symptomless cases, there were two where bleeding, independent of urination was the only symptom, and seven where the chief complaint was soreness or pain variously described as at the vulva, in the vagina or near

caruncle was the sole cause of this, although there was no later record to tell whether cure was effected or not. Six patients had had enough bleeding to lay stress on it in their story.

The duration of symptoms varied all the way from one week up to twenty-one years, but the majority dated their troubles back from three to fifteen months.

In the cases where pain or bleeding was the main complaint it seems obvious that the tumor itself, existing as an irritating foreign body, was the direct cause of the symptoms and that its removal would cure these symptoms. But in the cases where the urinary symptoms existed, it did not seem quite so clear that the tumor was of itself the sole factor. To be sure, several cases returned a year later with no recurrence and no symptoms, and it is easy to assume that the caruncle was the original cause of symptoms. But a few cases also returned where the tumor was gone but the symptoms had never been changed in any way. These cases are few in number, but a close study of all the available data fails to show good and sufficient cause for the persistence of the trouble. The urines were all clear and clean without albumen. The patients had no pelvic symptoms made out in a routine pelvic examination. The age varied, and though all were over thirty-five, none were suggestive of the old woman's irritable bladder.

Recurrence. Twenty-three patients, or practically one-third, had had various operations for the removal of similar growths before coming to the hospital; three of these had had "several," five had had two, and the rest one attempt at a permanent cure. The ages of those patients showing a recurrence varied all the way from eighteen to sixty-three years, and the evenness of the distribution over this period shows that age had nothing to do with recurrence. Nor does the type of the first operation seem to have any bearing on the result, as excision and cauterization, either with the actual cautery or with chemicals, had been used about equally. In those cases where there was a strictured urethra not remedied at the first operation, the caruncle always returned, but, other than this, no cause for recurrence could be determined. Of recurrence after leaving the hospital, no accurate data are available, but several were reported; and one recurred as cancer which was cauterized the first two times.

Age. The youngest patient was six and the oldest seventy-three years. All but thirteen were over thirty and only one over seventy. Between thirty and forty, there were fifteen; between forty and fifty, 14; between fifty and sixty, fourteen; and between sixty and seventy, fourteen cases. The age seemed to bear no relation to symptoms or to pathology. It is interesting to note that both the children had no symptoms though the growth was in both cases of good size.

One object in looking over these cases was to see how close a connection there was between

stricture and caruncle. Of the four cases of stricture of the female urethra operated on in the last twenty years, two had caruncles, and of the caruncle cases where data were given regarding the patency of the canal, only three had any narrowing of the urethra. But it is interesting to note that these five had all been operated on before and had recurred, but after the stricture was cut or dilated, four were cured and one was not heard from again. It is important then to make sure that the canal is free in order to eliminate one factor which apparently causes recurrence.

Etiology. There was nothing in this study which throws any light on the etiology of this growth. In one case only was trauma given as the starting point of the symptoms. Infection might seem to play a more or less important part in certain cases if we could assume that a form of new growth which consists of dense granulation tissue would be most likely to arise from the irritating effects of a local infection, but this is certainly not always the case, as two of the three cases where the canal was strictured, and hence where there must have been infection, showed on pathological examination definite papillomatous growths and not granulomata. Beyond this, nothing can be suggested as to cause.

Treatment. Very little need be said about treatment. Removal is the thing aimed at, and how it is done seems to make very little difference. If they are small the actual cautery disposes of them efficiently. If they are large they should be removed and the base sutured; in certain cases where they surround a large part of the circumference, the urethra should be resected and the ends sutured together to prevent later stricture. And in all cases sounds should be passed to the bladder to make sure that no narrowing of the canal is present. High frequency cauterization of these grows has been advocated and though I have had no experience with it, it would seem worth trying. Because of the possibility of malignant degeneration, it would seem wise to excise when possible and examine pathologically.

Summary. Pathological examination of these tumors show a surprisingly large percentage of cases in which the question of malignancy is raised and as there is clinical evidence to show that certain cases turn out carcinomatous later, from the evidence of this report, it would seem wise to examine all specimens when possible and watch carefully those suspicious ones.

About 50% of caruncles have no accompanying symptoms and where urinary symptoms are present a large proportion are probably not due to the growth.

Thirty-three per cent. of all cases of this series have recurred regardless of the type of operation and where a stricture has been present it has always recurred.

Clinical Department.

CUTANEOUS TUBERCULOSIS. REPORT OF A CASE OF FOLLICULIS AND ERYTHEMA INDURATUM.

By J. H. BUFFORD, M.D., BOSTON.

Physician, Dermatological Dept., Boston Dispensary.

AND

C. G. LANE, M.D., BOSTON.

Assistant to Physicians, Dermatological Dept., Boston Dispensary.

E. P. Age, 20. Born in Russia. Salesgirl—underwear.

P. H. Eight or nine years ago the patient had an operation on the left side of her neck and a gland was removed.

P. I. Three months ago she noticed "pimples" on both arms. One or two appeared at first on the upper arm and then the eruption gradually spread over both arms and hands. One month ago much the same condition appeared on the legs and has become much worse in the last two weeks. She has complained of much pain on walking and moving about, but she has been comfortable on sitting or lying down. She has felt fairly well and has slept well. Her appetite has been excellent and her bowels have been in good condition. The glands in her neck have been slightly swollen in the last couple of weeks.

P. E. On examination the girl appeared sick, walked as if with effort, and was generally untidy and dirty. Inspection showed diffusely scattered papules, often slightly tender, over the upper arms, forearms, and hands, more marked on the extensor aspects, especially of the forearms and hands. The papules were small, 2 or 3 mm. in diameter, usually acuminate, dull red, with usually a crusted top which tended to be slightly dark colored. The apex of these lesions was sometimes vesicular and often pustular. In other lesions, the dark colored, centrally adherent crust was noticeable. There was a tendency toward grouping on the backs of the hands where there were four or five pustules on the same reddish, slightly raised base, forming areas about 1 cm. in diameter. Some of the larger lesions were fairly tender and looked as if they might contain a drop or two of pus. The skin about the nail of her right forefinger was red, tense, tender, and swollen as if it were the beginning of a paronychia. There were only a few lesions on the body. Here, as well as on the arms and legs, was an amount of black material inconsistent with the proper use of soap and water. Some of the older lesions on the arms had apparently run their course, and were flat, purplish, slightly atrophic as if a small white depressed scar would be formed there after a certain length of time. Here was presented a picture in which each individual lesion from its start as a dull red papule to its termination in a more or less slightly depressed atrophic white-ridged scar had lasted apparently from six to nine weeks or thereabouts, during which time the center of such had become more or less necrotic.

The legs presented a somewhat different appearance. Numerous lesions were somewhat similar to

those on the arms but were in general a bit larger, a bit more indurated, and more tender. The calves of the legs were distinctly indurated, purplish in color over large areas, and in the center of these purple areas were large ulcers. There were four or five of these on each calf. They had apparently been neglected and were rather deep, punched out, indurated ulcers with a sluggish, dirty gray base with rather a foul discharge showing, here and there, a tiny red point. The area about these ulcers was rather tender to the touch. The ulcers were irregularly oval with sharp edges which descended rather abruptly but were not undermined. They varied from a quarter of an inch in diameter to three-quarters of an inch in diameter. The base of the ulcer was flat and, as I have said, dirty gray in color, the induration extending about them an inch and a half or two inches.

It was thought at first that the case was a pus infection and that it would clear up quickly with soap and water plus tonics and a betterment of the general condition. The condition was obstinate and gradually cleared up during several weeks' treatment, making the most progress under a general tonic treatment combined with a weak iodine solution on the arms and a chlorinated soda solution for use on the legs. The patient disappeared from the clinic, but, at the last visit, the general condition was improved, the arms showed few lesions, and the ulcers were cleaner with less discharge, though there was considerable pain on moving or walking. The lesions, with the history and progress of the condition, warranted the diagnosis of a cutaneous manifestation of tuberculosis showing itself in two forms—the so-called "Folliculitis" on arms and hands and Erythema Induratum on the legs. This diagnosis was later confirmed when the case was exhibited at the Boston Dermatological Club.

Almost yearly, for several years, newly recognized cutaneous manifestations of tuberculosis appear in print. While this paper does not deal with those of most recent date, it does have to do with forms of cutaneous tuberculosis which we believe are often unrecognized and, therefore, of sufficient interest to report.

Reports of Societies

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

MEETING OF WEDNESDAY, FEBRUARY 3, 1915, AT 8 P.M.
THE PRESIDENT, DR. JAMES C. WILSON, IN THE CHAIR.

MEYERIAN LAWS OF HEREDITY AND THEIR APPLICATION TO EUGENICS.

DR. ALFRED GORDON: Historical reference is made to Darwin's Origin of Species and to the principle

of "Natural Selection," also to Weissman who insisted on proof of the hereditary transmission of acquired characters, to the work of deVries, and to the teachings of Mendel. The fundamental principles of heredity as laid down by Mendel are considered and applied to the investigations in the domain of plants and animals. Special stress is laid on the principle of segregation of unit-characters, on their non-disappearance in subsequent generations, on their existence in a latent shape in individuals who happen to be deprived of them. Two personal observations are mentioned of polydactylism in one of which I succeeded in tracing the abnormality in four generations, and in the other case for three generations. Other abnormalities are discussed and pathological conditions all following the rules of inheritance discovered by Mendel. Reference is also made to the work of other observers regarding mental disorders in which the above laws also find their applications. Special attention is called to the proper understanding of breeding and crossing. The phenomenon of heredity is a phenomenon of individuals, controlled by precise and specific physiological laws. Measures of precaution and of prevention are mentioned. The entire problem of eugenics depends upon the fundamental knowledge of the laws of heredity.

A STUDY OF THE COMPARATIVE TOXICITY OF THE VARIOUS MERCURIAL PREPARATIONS.

BY DR. JAY FRANK SCHAMBERG, DR. JOHN A. KOLMER AND MR. R. W. RAIZIES, PH.D., (BY INVITATION.)

DR. SCHAMBERG: From our work we have reached the following conclusions:

1. Rats exhibit such variation in their resisting power to mercurial salts that too much weight should not be attached to minor differences in toxicity in the experimental findings.

2. While the maximum tolerated dose of the various salts may be widely divergent, when the doses are calculated in the terms of pure mercury, they fall within relatively narrow limits.

3. In general terms, it may be stated that the toxicity of the various mercurial salts is directly proportionate to the amount of pure mercury contained.

4. The inorganic salts, as represented by the bichloride of mercury, are no more toxic than the numerous organic combinations that are commonly employed.

5. The differences in the molecular structure of the mercury compounds tested by us were found to be of relatively little importance as affecting their toxicity.

6. The bichloride of mercury was fatal on the average in intravenous doses above two milligrams per kilo of body weight; administered intramuscularly it was fatal on the average above six mg. per kilo. of body weight.

7. The average relationship as to the toxicity between the intravenous and intramuscular administration of mercury was 4:1.

8. The insoluble preparations such as gray oil, calomel and the salicylate of mercury are absorbed at the rate of a little over 1% of the injected amount per day.

9. Even at the end of six or seven weeks, almost 50% of the mercury of insoluble preparations may be unabsorbed at the site of the injection.

10. The injection of the usual doses of insoluble mercurial compounds at weekly intervals, must invariably lead to accumulation of the drug in the tissues.

11. Insoluble mercurial injections should be given only by the skilled physician after careful consideration of the dose and of the intervals of administration.

12. Mercury has a great affinity for the cells of the kidney and this organ is one of the earliest involved in mercurial intoxication. Hence during the intensive treatment with mercury the necessity of careful examination of the urine from time to time should be emphasized.

DISCUSSION.

DR. H. A. HARE: I think the gentlemen presenting this subject have rendered a distinct service, not only by this contribution of original work, but in calling attention to a fact which those of us who have had our attention centered upon this matter have long recognized and which has not been generally recognized by medical men, namely: that mercurials are dangerous in the acute and subacute types of nephritis, to such an extent that for a goodly number of years I have always, before administering mercurials, except possibly small doses of calomel, followed the dosage by salines, sweeping them out. I have always had the urine examined microscopically and if red blood cells were present or there was the slightest evidence of acute lesions in any part of the kidney, I put mercury aside with even greater rigor than I would put arsenic aside if some such combination of drugs had been suggested for the case. This point was particularly impressed upon my mind by a case of syphilitic nephritis, due to virulent syphilitic infection, in which the patient suffered from hematuria and in which the history was that on three occasions when given mercurial injections the hematuria greatly increased and the man suffered great pain over the kidneys. The so-called cumulative effect of mercury, I think also does not receive the attention it should. In view of the exceedingly slow progress of its elimination from the body proportionate caution should be observed in its employment.

DR. ROBERT N. WILLSON: It may be of interest to cite two cases of uremia occurring in the wards of the Philadelphia General Hospital, both of chronic intestinal nephritis, and both resulting from the administration of about two grains of calomel. One died in uremia. The other recovered from a fully developed state of uremia. I have also studied with interest a third case, one of pericarditis in a young colored boy who received by error 64 grains of calomel within three days. That boy also died, and microscopic sections of his kidneys showed the typical *verkalkte Niere* of the Germans, very much the same condition as that seen in the kidneys of the rats shown by Dr. Kolmer. I have a large number of specimens made in Vienna from the kidneys of patients treated in the luetic wards with mercury, all of which show the same type of kidney. During the last two or three weeks I had the privilege of seeing with Dr. Jump a young woman who presented a curious combination of cardiac and neurasthenic symptoms, but whose apparently normal kidneys functionated perfectly as far as we could determine. Shortly after the ad-

ministration of a small dose of calomel she vomited, the urinary flow ceased, she went into uremia and died. This is the fourth case which I have personally studied inside of a brief period poisoned by small doses of calomel. These occurrences have an especial interest in the light of a statement made to me recently by an old lady who grew up in the South, to the effect that in her young days she was frequently given a teaspoonful of calomel as a dose; and that it was not an infrequent thing for the physicians to prescribe even larger doses of the drug.

DR. DAVID RISEMAN: I should like to ask Dr. Schamberg whether a soluble preparation injected into the tissues does not become an insoluble preparation. I am glad he has called our attention to the over-use of mercury in nephritic cases.

DR. JAMES M. ANDERS: I should like to ask Dr. Schamberg whether he can recommend any special preparation of mercury for hypodermic use. I understand him to say that the salicylate belongs to the insoluble group of mercurial salts. This is the preparation I have been in the habit of employing hypodermically with, as I have reason to believe, excellent results, although in some cases inunctions have given even better results. I would also ask him what would be the proper interval between the injections in view of the cumulative effects of the drug.

DR. SCHAMBERG, closing: The injection of a soluble salt of mercury into the tissues would, as Dr. Riesman suggests, doubtless lead to the formation of an insoluble compound; but this must be more or less rapidly reconverted into a soluble combination, else it could not be carried through the blood stream, influence the tissues therapeutically, and be eliminated through the kidneys. It must in the end become soluble, no matter what the primary local change is. I believe that inunctions constitute the safest method of employing mercury in massive doses. Professor Welanders of Stockholm claims that much of the effect of mercurial inunctions is due to absorption of the mercury by the lungs, that there is a volatilization from the skin, with inspiration through the respiratory tract. Regarding Dr. Anders' inquiry of the best preparation of mercury to be employed for injection, I may say that the conclusions which we have given do not necessarily apply to the human subject. I think insoluble mercury compounds ought never to be injected oftener than once a week. If the dose is large, not oftener than every two weeks. Careful examination of the urine should be made from time to time in patients who are receiving mercury. In rabbits that received daily intramuscular injections of mercury over a period of 48 days, the kidneys showed microscopic pathological changes after autopsy, although during life albumen was only irregularly present in the urine. I think the medical profession is not sufficiently awake to the fact that mercury is a powerful kidney irritant. The two organs for which mercury has the greatest selective affinity are the liver and kidneys. This is not necessarily because it is eliminated through these organs, but because it is powerfully renotropic. I recall a patient whom I saw with Dr. John W. Swan some years ago, who received at the hands of another physician mercury by inunction, by injection and by mouth at the same time for a supposed luetic eruption. She developed a severe nephritis with anasarca and Dr. Swan who analyzed her

urine daily found that she continued to eliminate the drug for 127 days after the last dose of mercury had been ingested.

REPORT AND ILLUSTRATION OF A REMARKABLE CASE OF HOUR-GLASS STOMACH.

By DR. H. A. HARE AND DR. J. CHAMBERS DaCOSTA.

DR. HARE: Dr. DaCosta expected to present the operative details in connection with this case, but he is unable to be here. My name is connected with the case largely out of courtesy because the patient was under my care. The patient was a man of about 48 or 50 years of age, who suffered from severe pain in the upper zone of the abdomen. The diagnosis was obscure upon whether the condition was a malignant growth or ulcer. The x-ray photograph produced this very extraordinary manifestation of hour-glass stomach. It is difficult to conceive of a deformity greater than the one shown which could be produced by disease. The points which Dr. DaCosta expected to discuss were those of the proper surgical procedure in a case of this kind. As a matter of fact he ignored the extravasation except to close the perforation. He ignored the fibrous band between the upper and lower parts of the stomach by anastomosis. The man died three or four days following operation from pneumonia at the base of the lung on the side of operation. The x-ray picture is such an unusual one of an hour-glass stomach that we thought the case worthy of presentation to the College. I regret that Dr. DaCosta is not here to discuss the problems in surgery which he wished to bring before the Fellows of the College.

PHYSIOLOGICAL CHARACTERISTICS IN INSANITY.—THE THYMUS AND THE PITUITARY IN DEMENTIA PRÆCOX.

DR. S. D. W. LUDLUM: In a group of cases of dementia præcox Abderhalden reactions were obtained, in some cases to testicle and pancreas, in others to testes and thyroid, while in others no reactions were obtained.

In the individuals who gave the reaction to testes and pancreas the following physiological symptoms were observed: Leukopenia in exacerbations, leukocytosis in improvement, increased blood pressure, pulse feeble and rapid, temperature, two degrees above, exaggerated knee jerks, diminished cutaneous reflexes, increased electric reactions of muscle, tremor of tongue and extremities, increased weight, later loss of appetite, Westphal's Pilez pupillary sign, nutritional variations, temporary spastic legs, increased mechanical irritability of muscles. These symptoms are comparable to those obtained in animals after thymus-ectomy. In the schemata of interrelationships of glands to internal secretions the over-activity to testes and pancreas is consistent with underactivity of thymus; also the thymus of a dog whose thymus had been removed gave positive Abderhalden reactions to testes and pancreas. Several cases of this type cured with thymus extract. The majority of those cases which gave no Abderhalden reaction had the physiological and morphological characteristics of dyspituitarism and improved with pituitary extract. Those cases giving the reaction to testes and thyroid were of the catatonic type. In addition to these forms there is a hyper-pituitary mental disturbance which has its prototype in a mentally retarded girl of five years who has the stature of eight years of age. Her serum reacts only to the pituitary gland and she

represents the beginning of gigantism. The prototype is followed by cases in adults who exhibited unusually large skeleton growths and reversal of sexual characteristics with the mental symptoms of hypomania. The treatment of these cases can be successfully carried out if the case is sufficiently studied.

CLINICAL CONFERENCE OF THE NEUROLOGICAL INSTITUTE, NEW YORK.

REGULAR MEETING FEBRUARY 25, 1915.

J. RAMSAY HUNT, M.D., in the chair.

HYPOPHYSECTOMY WITH ACROMIKRIA.

DR. WALTER TIMME presented from the Third Division a case of hypopituitarism with akromikria. The patient was an unmarried woman 34 years of age who began eight years ago to have pain in the right leg. This gradually became worse, involving successively the other leg and both arms, so that eventually she became unable to move about and finally took to her bed. During the same interval the various joints became swollen and their range of mobility gradually lessened to such an extent that she could flex the knee-joint only sufficiently to lift the knees from the bed about three inches. Both ankle joints were similarly affected, as were the wrists,—and to a limited degree, the elbows. During this entire time she had been treated at various hospitals and by various methods, including massage, baking and hydrotherapy, and thymus gland had also been administered. Occasionally there had been temporary improvement, but no definite turn for the better. She entered the Neurological Institute some three weeks ago in the condition described above. Upon closer inspection and investigation, it was found that, not only were the joints tender and much swollen, but both feet and hands were small in undue proportion to her size. The fingers tapered rapidly, resembling spindles. Other abnormalities of bony growth were seen in the prognathous upper jaw, the retreating chin, and the closeness and crowding out of line of the teeth. Furthermore, she gave a history of diabetes in the mother and an inordinate desire for sweets in herself. She had polyuria and polydipsia, but no glucose appeared in the urine. Her skin had a glossy appearance, and while not truly edematous, as it did not pit on pressure, yet there seemed to be some infiltration of the subcutaneous tissues which did not rob them of their elasticity. Her menses were normal and her internal organs seemed sound. Her blood pressure was 140 mm. X-ray plates of the joints showed changes in the bony structure resembling osteoarthritis, also in the structural lines of the bony tissue, indicating some rarefaction. These features, especially the smallness of the hands and feet—acromikria, placed the case indubitably in the hypopituitary class. Whether the original etiological factor was an hereditary one—diabetes in the mother—or whether in adolescence an over-developing ovary was concomitant with a non-developing pituitary gland giving rise to the patient's senility, can hardly be established. After a few weeks of treatment with graduated doses of whole gland substance together with small doses of

thyroid gland, the patient gradually improved until she was able, with assistance, to stand on the floor and to walk some few steps. She was able to flex both knees, so that she could lift them almost a foot from the bed in the prone position, and was also able to flex and extend her feet to a limited extent. The swelling had largely left the joints, with the exception of the left ankle, the pain had almost gone, and she felt extremely hopeful and gratified. In such cases the prognosis for a permanently good result in so far as locomotion is concerned, is only fair. The changes in the joints and bones at this time of life are rarely to be overcome to any great extent by any means known to us. The swelling and pain are relieved usually and some degree of motion restored, but the patient remains more or less helpless. Organo-therapy offers the best means of combating the condition, the difficulty being to find the original gland at fault, and not simply the apparent one. If this cannot be done, the improvement is very slow and relapses occur.

A CASE OF KORSAKOW'S SYNDROME WITH CEREBRAL SYPHILIS.

DR. H. K. MARKS presented from the First Division a clerk, 30 years old, who had contracted syphilis in 1909; otherwise his past history is negative. He has taken no alcohol or drugs.

For three months following the appearance of the chancre he was treated with mercury internally and by inunctions, later by salvarsan and with mercury intramuscularly.

His present illness dates from the summer of 1914, when he experienced a sensation of numbness and coldness involving the entire left side of the body. There was no impairment of motor power, and his reflexes are said to have been unaffected. He was put on mercurial inunctions and injections and increasing doses of potassium iodide. After a couple of months he felt quite normal again.

Beginning the second and third weeks of December, 1914, he began to complain of persistent headache, dizziness, slight impairment of memory. On Dec. 25 he is said to have been quite ill with headache of unusual severity, occasional twitching of the trunk and vomiting. On Jan. 12, 1915 he was forced to quit work. Two days later it was noticed that his mouth turned to the right when laughing and that his left arm and leg were slightly weak.

On Jan. 18 he was admitted to the Neurological Institute. Physical examination gave the following positive data: Pupils moderately dilated, slightly irregular, reacting to light through a small range, but well to accommodation. The tongue was slightly tremulous; there was slight unsteadiness of the outstretched hands; a positive Hoffman sign on the left; a somewhat exaggerated ankle jerk and extensor tendency of the great toe on the left side. Otherwise the physical examination was quite negative. The remaining reflexes, superficial and deep, were active, not exaggerated, and equal right and left. Lumbar puncture revealed a positive Wassermann reaction, globulin in excess, and 30 cells. The serum Wassermann was negative. The evening of Jan. 22, the patient suddenly developed a right hemiplegia. When examined the following morning he was found to be aphasic; the right pupil and the lid aperture of the right eye were larger than the left; the pupils reacted well to light and accommodation; right mouth facial weakness existed; the tongue, however, was protruded straight.

The right arm was completely paralyzed, already slightly hypertonic. The arm reflexes, right and left, were now brisk, though greater on the left. The Hoffman sign, marked on the left, was suggested on the right. Pronounced rigidity of the abdominal wall existed, and the reflexes, epigastric and abdominal, could not be obtained.

The right leg was paretic. Partial range of motion remained. The tone was flaccid. The deep reflexes, right and left, were exaggerated, but here, too, were somewhat greater on the left. Well marked clonus existed on the left. A suggestion of clonus on the right. Typical Babinski was present right and left. The patient coöperated well during examination, apparently hearing and understanding everything.

Since this date there has been no further accident, the whole tendency has been toward gradual improvement.

We have, then, the history of a young man who, five years after infection, despite vigorous anti-syphilitic treatment, develops symptoms referable to cerebral involvement, *i.e.* headache, dizziness, vomiting, blunting of memory, sensory and motor hemiplegia. The case up to this point presents little or nothing out of the ordinary.

A more unusual condition, however, is revealed by an inquiry into his mental condition. We have already mentioned a general blunting of memory, first observed by the patient and his friends in December, 1914. On Jan. 15 he surprised his family by asking for his dead father, whom he thought living. Believed people had been to see him who had not, that his brother was still living at home. He recognized everybody and spoke intelligently when questioned.

Two days later he appeared slightly expansive, said that he had three fountain pens, that he had secured several positions for a relative on the stage. His discourse was otherwise intelligent and according to fact. A couple of days later he asked for various articles of clothing which he had bought "just the other day," articles which were not new.

According to a friend who had observed him closely, his memory for past events was excellent but poor for current events, his discourse intelligent, speech not thick. He recognized people, pictures, objects. He was able to read correctly a few newspaper headings shown him and enjoyed jokes.

A study of his mental condition revealed during his first four days in the hospital, that is, up to the time of the stroke, Jan. 22, the following:—

First of all and most striking was a disturbance of what the Germans term *Merkfähigkeit*. He was quite conscious, he was able to understand perfectly everything that was said to him. His emotional response and general coöperation were good, his memory for past events without serious defect. Yet there appeared a definite disturbance in his ability to gather together new impressions or experiences, and to acquire a sequential picture of them. On the morning following his entrance to the institute he had already been there four days, he made the acquaintance of the doctor for the first time, though he had seen him twice before. He did not remember whether he had had his breakfast, or again, what he had eaten for breakfast. On another occasion the doctor was the masseur who treated him every other day. He had been moved in from another ward, etc., etc.

Associated with this was a disturbance of orien-

tation as to time and place. He had been in the hospital 24 hours, 4 days, 8 weeks; the month is February, 1915; November, 1914; January, 1916; he was taken ill in November, 1915. When his attention was called to these discrepancies he more frequently recognized them than not and made the remark that something must be wrong. The Neurological Institute is the Polyclinic, the Presbyterian Hospital, the Garcia Hospital (a man named Garcia occupied the adjoining bed).

On a number of occasions he indulged in pseudo-remiscences or placed actual events in a false time relationship with the conviction of reality. Two days after entering the hospital he had dropped in to visit his physician the night before; then he had gone home and written a letter to the single tax party; he had been to see a friend the night before who had gone to a dance; he had just arrived this morning (he had been in the hospital a week). The experience would usually be related in a general way, and when the patient was pinned down he had a response to the smallest detail. Frequently, when confabulation was not spontaneous it might be induced.

The same applied to certain auditory and olfactory hallucinations which could be induced during the first few days of the stay in the hospital. When it was suggested that there was a flower in his hands he smelt the odor of roses or violets. When suggested that the tick of a watch was the buzzing of an insect, he described the insect. For two or three days following the stroke, Jan. 22, no confabulating tendency could be discovered. He appeared also clear in orientation and in time references.

At present his mental disturbance no longer has the sharpness of its earlier outline. He is oriented as to place, has a fair grip on current impressions and no pseudo-remiscence can be induced. Time relationships are, however, still greatly affected.

Taking these mental impressions as a whole, then—the disturbance and the ability to retain or arrange new impressions, a greater or less regressive amnesia, a disturbance in orientation for time and place, a tendency toward confabulation—we see that we have a syndrome conforming in outline to the Korsakow symptom-complex. The condition, though not rare in syphilitic mental disorders, is still unusual enough to justify calling your attention to the case.

A CASE OF PITUITARY TUMOR.

DR. FOSTER KENNEDY presented, from the Second Division, a man aged 50, who was admitted to the hospital complaining of difficulty in vision, and pains in his legs with occasional headache. He is married and has seven children. No history of lues. Is a man 6 feet 1 inch, with large skeleton. Two and one-half years ago he began to complain of irregular aches and pains about his hips and in his legs. These were worse at night and were not constant. He has been treated for sciatica because of them. About the same time he began to have difficulty in seeing small print. He felt "as though there were a veil over his eyes." The onset of this was gradual over a period of about two months, but since then he has noticed no change for the worse. He has had occasional frontal and parietal headache for the past six months. He has noticed no change in his sexual power or desire. He is generally weak but thinks that this is the result of lack of exercise. His pupils are normal. The optic

disks show a slight pallor and there is a well marked bitemporal hemiachromatopsia with a small defect of similar character for form. His cranial nerves are otherwise normal, and beyond an inability to obtain the ankle jerks there do not seem to be any abnormal neurological signs. A test of 250 grs. of leviculose failed to produce any glycosuria. X-ray examination of the skull shows marked loss of the outline of the sella turcica, which was very much broadened and shallow. His cerebrospinal fluid is normal. Wassermann reaction in blood is negative. A diagnosis has been made of tumor of the pituitary body. The question of whether or not to perform a decompression operation of the sella turcica is broached, but it is the opinion of the staff, that unless very definite signs of progression appear and considerable advance takes place in his symptomatology, it would be inadvisable to operate at this time. Experimentation towards discovering if posterior lobe feeding will produce changes in his bitemporal hemianopia goes forward.

Book Reviews.

The Pocket Formulary for the Treatment of Disease in Children. By LUDWIG FREYBERGER, J.P., M.D. (Vienna), M.R.C.P. (Lond.), M.R.C.S. (Eng.). New York: Rebman Company. 1914.

This fourth revised and enlarged edition makes again available a convenient pocket formulary which had, for some time, been out of print. It is adapted to the British pharmacopeia and is intended to afford concise and convenient information on the treatment of diseases of children by drugs. The text is alphabetically arranged and adapted to the British pharmacopeia. An appendix contains a table of poisons with their symptoms and treatment. References are also here included to von Pirquet's test and the tuberculin treatment for tuberculosis. This manual is naturally of greater value to British than to American practitioners.

Laboratory Manual for the Detection of Poisons and Powerful Drugs. By DR. WILLIAM AUTENRIETH, Professor in the University of Freiburg, i. B. Authorized translation of the completely revised fourth German edition by WILLIAM H. WARREN, Ph.D., Professor of Chemistry in Wheaton College. With 25 illustrations. Philadelphia: P. Blakiston's Son and Company.

The work of Autenrieth has been so long a standard in forensic chemistry that we welcome its introduction to the English speaking world in this translation. The work is well done and many shrewd comments by the translator make it even more valuable than the original. There is an absolute absence of circumlocution, and the simplicity of the language employed brings

every statement home to the seeker for information.

The Stas-Otto method for the isolation of organic, non-volatile poisons is employed, rather than the more cumbersome one of Dragendorff, and the newer medicinal agents, phenacetin, veronal, etc., are included in the scheme. Too much stress is laid on the methods of isolating minute, almost infinitesimal quantities of arsenic, for, though the translator insists that there is no such thing as normal arsenic in the body, yet Emerson was obliged to go outside of our city to find individuals whose urine would not show a trace of this poison by the very delicate method which he employed, and coarser and less searching means are more suited to toxicological examinations for forensic purposes. Attention is called to Lloyd's reaction, the similarity of hydrastin and morphine together to strychnine when treated with sulphuric acid and potassium bichromate, which Lloyd made the motive of his novel, "Stringtown on the Pike." Ptomaines, those bugbears to the inexperienced toxicologist, particularly when working with decayed material, are treated very briefly and dismissed with the assurance that they are easily distinguished from the alkaloids which they so closely resemble, without giving more than superficially the reasons for this assurance. There is also an excellent description of the quantitative estimation of alkaloids in crude drugs and their preparations.

An Introduction to the Study of the Endocrine Glands and Internal Secretions. By SIR EDWARD SCHÄFER, Regius Professor of Physiology in the University of Edinburgh. California: Leland Stanford University. 1914.

This monograph, the eighteenth in the series of Stanford University Publications, represents the author's five Lane medical lectures at the University in 1913. One of the earliest monographs on endocrinology was that in French by Dr. Naamé, which was reviewed in the issue of the JOURNAL for May 15, 1913 (Vol. clxviii, page 735). Dr. Schäfer's work, besides placing the data of internal secretion within easy access to English readers, rests on a fundamental experimental basis, while that of Naamé is empirically therapeutic. The five lectures deal respectively with general considerations, the functions of the thyroid apparatus, the functions of the adrenal apparatus, the pituitary body, and the internal secretions of the pineal gland and other of the endocrine glands. It is becoming an axiom of physiology that we are physically and intellectually what we are made by our internal secretions. It remains for therapeutics to continue what has already so brilliantly been begun in the domain of the thyroid, and apply the treatment of functional and organic disorders of the endocrine glands to the correction and relief of the disturbances which they produce.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JUNE 3, 1915.

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries beyond the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

THE WORK OF THE PUBLIC HEALTH COUNCIL OF NEW YORK STATE.

In our issue for April 29 reference was made to the value of the organization in New York of a public health council to coöperate with the state department of health. Since then there has been published the first report to the governor of this council, presenting an account of its work from its creation in 1913 to December 31, 1914. After prescribing the qualifications for directors of divisions, for sanitary supervisors, and for public health nurses, the council recommended that the position of sanitary supervisor should be placed under civil service rules and presented a list of experts from which the civil service commission might select special examiners to assist in the examination of candidates. The commission selected Professors C. E. Winslow and W. H. Park of New York City. The examinations were held, and the names of

the eligible men were announced in April, 1914. The council next turned its attention to framing a new sanitary code for the state, and for several months was engaged in this important work, at its stated meetings and at frequent informal meetings of sub-committees, as well as on the part of individual members to whom were assigned special subjects for study and report. In the preparation of this code it was the constant aim to secure to the citizens of the state all the advantages which science and experience, especially during the last quarter of a century, have offered in the prevention of disease, and in the promotion of the common welfare, with the least interference with the business, comfort and convenience of the people concerned. It was necessary that its new provisions should not conflict with, but be adapted to and supplement, the various provisions of the public health law already in force, not only in the health, but in other executive departments of the state. The council, furthermore, sought to eliminate from the state sanitary code—and this was especially necessary in the chapter dealing with communicable diseases—the useless sanitary procedures which mark the views and practices of an earlier day, now replaced by exact knowledge; and to abandon, in its text, those technical terms which, though still often employed, have lost their former meanings and values, as well as those which are not readily comprehensible by the citizens for whose use and guidance the code is framed. Thus the hope is entertained that this new sanitary code will prove to be effective, intelligible, and not unduly rigorous in view of the large advantage to all which the adoption and enforcement of a modern scientific code promise.

In the chapter on communicable diseases the requirements as to the prevention of the spread of disease and the suppression of epidemics sum up, it is believed, the practical achievements of many years of scientific discovery and experience by certain precautions and regulations, which center in intelligent cleanliness. The older and most of the existing sanitary codes have much to say about quarantine and disinfection, while this code concentrates attention on the care of waste material from sick persons, and others who harbor disease germs, and the proper modes of simple cleanliness, which protect the well and render quarantine and elaborate disinfection, with their attendant expense and annoyance, largely unnecessary. In preparing the chapter on milk and cream it was

the aim to make the requirements in regard to the grading of milk not inconsistent with the regulations of the New York City code, and an exhaustive examination was made of the provisions of that code and of those of various other municipalities throughout the country. Furthermore, to make the study of the subject as comprehensive as possible, a public hearing was held in Albany, to which leading representatives of the producers, dealers and consumers were invited. All milk is required to be graded according to the score of the dairy, and it was the sense of the council that to obtain the best results in the production and handling of milk, discretion, tact and good judgment, especially in the beginning, should be exercised by the local health officer in the scoring of dairies. It is believed that, by this procedure, not only may the milk supplies of the state be safeguarded, but also the interests of the farmer, through such adequate pecuniary returns to him as the improvement in the quality of his product may justify.

In regard to the chapter on labor camps, it is stated that the existence throughout the state, especially at certain seasons of the year, of a large number of labor and construction camps creates a peculiar and difficult factor in the health work of the commonwealth; but the opinion is expressed that the camp regulations which have been formulated will serve, without imposing undue burdens upon private campers or those responsible for labor or construction camps, to protect the citizens against certain pollutions of water supplies and serious nuisances, heretofore not infrequent. The question of the suppression of nuisances has often been the bane of the local health officer's administration. The council believes that this is largely due to doubt on the part of local health authorities as to their duties and powers under the law, and that when the machinery provided by a chapter of the code which is devoted to nuisances is put into effect it will be the means of affording much needed relief to a very large number of the population. The last chapter thus far enacted is entitled "Miscellaneous," and it includes regulations, similar to those in force in the more enlightened states and cities of the country, relating to spitting, the common drinking cup and towel, and barber shops.

In the concluding portion of the report it is stated that one of the most important subjects at present engaging the attention of the council

is the fixing of qualifications of local health officers hereafter to be appointed. It is felt that this matter goes to the very root of effective health administration in the state, since the share of the individual citizen in the beneficent achievements of sanitary science and preventive medicine, and the direct advantage to him of a modern, effective public health administration, depend, in the end, upon the capacity, training, experience and devotion to the service of his local health officer. Owing, however, to the existing lack of facilities for the training of the health officer and to the comparative smallness of the salary—in view of the amount of labor involved in an efficient performance of the duties of the post—the impracticability is realized of adopting at present as high a standard as is desirable. It is the belief of the council that the solution of this pressing problem involves the education of physicians and others in modern preventive medicine by the creation of a school of young men interested in public health, who would form a source of supply of health officers. As a large number of trained health officers became available, it would be practicable to raise from time to time the prescribed standards. To attract efficient young men to this important public service it would, of course, be necessary to afford them attractive opportunity and adequate compensation.

In connection with this report a paper on "Organizing a Community for Public Health," by Professor Winslow, director of the division of publicity and education of the state department of health, which is also publishing *Health News*, is of great interest. The city or village or town, he says, is the place where the public health campaign must ultimately be fought and won, and it seems to many observers of the situation that correlation and coördination of local health activities is one of the most pressing needs. If there were a central health council in each community representing all these activities, it might serve as a valuable board of strategy for utilizing the various health forces to the best advantage. Such a council would, of course, have no power to control the action of agencies already in existence, but its meetings would serve as a clearing house for information as to over-lapping and to unfilled needs. It would give to all its constituent organizations a better view of their work in relation to the whole problem, and the council, once formed, would be in a position to plan new health activities intelli-

gently and to bring an organized force of public opinion to bear for securing funds from either public or private sources. The representative men and women composing such a council would naturally become members of the American Public Health Association, so as to keep in touch with current progress in the health movement as a whole, and, with the advice of the local health officer and the state sanitary supervisor, they could determine what particular health need was most urgent in the community. In each instance public attention could be focused on this one end until it was attained.

THE PRODUCTION OF EMINENT MEN.

IN the issue of the JOURNAL for January 28, in an editorial on "The Biologic Aspects of Early Marriage," we commented on the theories of Mr. Caspar L. Redfield of Chicago, as outlined in his paper in the *Journal of Heredity* for July, 1914. In the issue of the JOURNAL for March 11, we commented further on Mr. Redfield's position and on some of the objections against it brought forward by Professor R. H. Johnson of Pittsburg, Pa. In a recently published pamphlet on "Great Men and How They are Produced," Mr. Redfield continues this discussion and in support of his contentions publishes a list of partial pedigrees of 571 eminent men. In 222 of these cases the pedigrees are extended for two or more generations. In every instance there is affixed to the pedigree a figure denoting the birthrank of the individual, by which is meant the father's age at the time of the son's birth. There are 860 individual birthranks included in this list and they average 40.7 years, tending to indicate, in so far as such statistics are to be regarded as significant, that the majority of eminent men are born of fathers of the age of 40. The distribution of 1800 children in the age periods of their fathers is indicated in a numerical table, and another similar table presents the ratio of normal births and births of eminent men to fathers in the various age periods. This distribution of births for ordinary men and for eminent men leads to a consideration of the chances of any given individual for becoming eminent, which, Mr. Redfield concludes, vary almost directly with the age of the father at the time of the child's birth. In conclusion Mr. Redfield summarizes his position in the two following statements: 1. Rapid

breeding inevitably and necessarily leads to the production of inferior stock, no matter what the original stock may be. 2. Slow breeding is an essential to the production of superior stock and, when properly used, inferior stock can be transformed into superior stock in about one hundred years and into eminent men in less than two hundred years.

It would seem that Mr. Redfield's conclusions are somewhat too sweeping, or rather, that he perhaps misinterprets the meaning of his data. It would seem more probable that the increased intellectual capacity and consequent eminence of the children of older parents is due rather to the improved environment made possible by the devotion of earlier years to the acquisition of more favorable material conditions than to any actual improvement of stock due to slower breeding. Moreover, as we have said in a previous editorial comment upon the question of early marriages, what is really desirable is not the production of the largest number of individuals of intellectual or other eminence, but of a community with a minimum of defectives and a maximum of physically and intellectually wholesome individuals of the most durable and most highly potential stock. Probably natural process can be trusted to produce the world's quota of eminent men, as it has always done in the past. What is much more important from the point of view of constructive eugenics, is to check the production and prevent the ultimate dominance of inferior stocks by measures which may lead to their ultimate eradication.

ANTITUBERCULOSIS WORK AMONG INFANTS.—

ON May 1 was inaugurated at the Preventorium for Children at Farmingdale, N. J., an extension to take care of infants suffering from tuberculosis. There are here at present 12 infants under the age of one year whose mothers have consented to leave them under care for at least a year. This action was brought about by the need of providing for the treatment of infants suffering from tuberculosis for whom no provision is made in the various institutions for sufferers from this disease. There are 200 children between the ages of four and 14 at the Preventorium in Farmingdale. An investigation of the homes of these children revealed the fact that forty infants were infected with the disease, in many cases being cared for by tuberculous mothers. It is expected that this addition to the hospital will prove its worth as an important part of the comprehensive campaign against tuberculosis.

THE NATURE OF STUTTERING.

THE nature of stuttering is a question which has been a constant source of interest for the physician who has been called upon to treat or to give advice concerning these cases. It is, therefore, not out of place to present some of the modern tendencies or standpoints in this connection. Many new books on this subject are making their appearance. The boards of education in various cities are attacking this problem with greater persistence and increased hopefulness. The propagation of the modern conception, such, for instance, as is to be had from the survey of such a paper as that of John Madison Fletcher entitled "An Experimental Study of Stuttering" in the *American Journal of Psychology*, Vol. xxv, is, it is plain, highly desirable, if not absolutely necessary.

The conclusions of this work shall here be presented. It is agreed that the motor manifestations of stuttering consists of asynergies in the functioning of the three musculatures of speech, namely, breathing, vocalization and articulation. Certain accessory movements, which become stereotyped in each person and which are associated with these asynergic manifestations, consist of clonic and tonic states of other muscles not affected in normal speech. Since it is found that there is a great variation in the type of asynergy and accessory movements in individual stutterers, we must conclude that there is no special type of breathing, articulation or vocalization which is definitely characteristic of stuttering. Disturbances of pulse-rate, blood distribution and psychogalvanic variations, appearing before, during and following the speaking period, and varying in intensity with the severity of the stuttering, accompany the motor disorder in stuttering.

It is found, however, that the essential condition taking part in the origin of stuttering is a complex state of mind, in which such inhibiting and depressing feeling as fear, anxiety, dread, shame or embarrassment play a dominant rôle. These mental states are probably both cause and effect—a veritable vicious circle thus being established.

Furthermore, the nervous state found in many stutterers is probably the effect rather than the cause of the condition. Mental attitudes and moods, the quality of mental imagery, attention and association come in for consideration in

addition to the states of feeling mentioned above.

In brief, as Fletcher states, it is "the affective and emotional experiences associated with the pronunciation of sounds, rather than the nature of the sounds themselves" which determines the rise of the stuttering.

In conclusion, then, it must be said that since stuttering is really dependent upon certain variations in mental state, it is fundamentally a mental phenomenon, consequently its study is primarily a psychological problem. A natural corollary is that the method of therapeutic approach must be mental.

AFTER-CARE OF CRIPPLED SOLDIERS.

No matter what degree of skill is used by the military surgeons, what competent nursing the wounded soldier receives or what gratifying results are obtained, war will always leave its trail of grim mementoes. It is sad to see a robust young mechanic go blithely to the front for a few months' campaigning only to return with stumps in the place of hands, unfitted to make his living by his technical skill, doomed to become a lifetime burden to society. For the war pension does not solve the problem. Even if the crippled veteran receives enough to enable him to exist in some degree of comfort, it is an unfortunate thing for him to be obliged to be dependent for many years on the government, to be no longer a productive member of society. Such a state of affairs inevitably saps his moral stamina; multiply his case by thousands and we find a drag downward on the nation.

What then is the solution of the problem? Obviously to fit these potential dependents for social usefulness. Where a soldier is so injured that he has become unfitted to earn his living by the same means whereby he earned it before enlisting, he must be given an industrial education not inconsistent with his disability.

This in itself presents a fascinating problem, comprising as it does the following questions: What is the prognosis of the injury received? What is the mental capacity of the soldier? What special aptitude has he that might be utilized? And lastly, what trade shall be taught him? The first two questions, and in some instances the third one, come within the province of the medical man, the last question should be

answered partly by the soldier himself and partly by industrial experts.

The Austrian Red Cross has established schools for the re-education of the crippled soldiers, four of which are located in Vienna. The preliminary reports from these enterprises are encouraging. Those in charge state that the soldiers take enthusiastically to the idea, finding it an agreeable substitute for gymnasium work. In some instances men spend hours learning to use tools, where formerly they had objected to a half hour at the exercise apparatuses. It is noticed also that the men are much more cheerful since these schools have been introduced, the work seeming to act as a mental tonic.

It has been found possible, in the cases of some skilled workmen who have been so crippled as to be apparently rendered incapable of carrying on their trades, to manufacture tools especially adapted to their conditions and thus restore their usefulness. Right-handed workmen, who have lost that member, have been taught to use their left hand instead. Some workmen who have lost their legs have been taught typewriting and the use of knitting machines. Other substitutes for the individual's former occupation will doubtless be found as the war progresses.

MEDICAL NOTES.

PREVALENCE OF MENINGITIS, PELLAGRA AND POLIOMYELITIS.—During the week ended April 24, seven cases of cerebro-spinal meningitis were reported in New York City, eleven cases of pellagra in Salt Lake City and three cases of poliomyelitis in Chicago.

LONDON DEATH RATE IN MARCH.—Statistics recently published show that the total death rate of London in March, 1915, was 21.2 per thousand inhabitants living. Among the several districts and boroughs the highest rate was 29.1 in Bermondsey, a populous region south of the Thames, and the lowest was 15.5 in Lewisham, a more open residential district on the same side of the river.

HOSPITAL BEQUESTS.—The will of the late Miss Elizabeth Thompson bequeathes, upon the death of the brother and sister of the deceased, equal shares of an estate of \$3,250,000 to the following institutions:—The Children's Aid Society, the New York Association for the Improvement of the Condition of the Poor, the Society of the New York Hospital, the Presbyterian Hospital, and Columbia University.

ACTIVITIES OF THE PENNSYLVANIA HEALTH DEPARTMENT.—During its annual session, which was adjourned on May 20, 1915, the Pennsylvania Assembly made a total appropriation of \$4,632,387 for public health work in that state during the next two years. Of this amount \$2,975,807 were for tuberculosis work.

In the campaign against tuberculosis, which ten years ago was the chief cause of death in Pennsylvania, 115 tuberculosis dispensaries have been established and three great state sanatoria at Mont Alto, Cresson and Hamburg have been constructed. In ten years tuberculosis has fallen from first to second place as a cause of death in the state and the rate is steadily declining year by year.

Four thousand deaths and 40,000 illnesses from typhoid fever was the annual toll exacted from Pennsylvania's citizens ten years ago. To-day this has been decreased more than 75% and although in the meantime the population of the state has increased more than a million, the number of deaths from this cause is only one-fourth the former figure.

During the past year the death rate of 13.9 per thousand inhabitants was the lowest in the history of the state. More than 78,000 people are alive in Pennsylvania today who would have died had the death rate of 1906 continued. Of these 78,916 lives, 40,528 have been saved by the reduction of the four principal diseases.

Typhoid fever	18,865
Tuberculosis	11,924
Diphtheria	4,648
Whooping cough	4,091

During these years, 1,767,000 babies have been born in Pennsylvania whose births have been recorded with all the facts concerning them in the Bureau of Vital Statistics of the Department of Health.

EUROPEAN WAR NOTES.—It is announced that the director general of the English army corps has accepted the offer of the medical schools of Columbia, Harvard and Johns Hopkins Universities to supply 32 surgeons and 75 nurses to administer a British field hospital, probably in England, possibly in France or Turkey. This expedition, which has developed from the suggestion of Sir William Osler under the approval of Lord Kitchener, will be primarily in charge of Dr. Walton Martin of New York, Dr. Edward H. Nichols of Boston and Dr. J. M. T. Finney of Baltimore. The British Government will bear the cost of equipment and transportation but salaries and all other expenses will be met by the respective universities. The first contingent, which is now being selected, will sail about the middle of June, its destination being as yet unknown. It is expected that the hospital of which the expedition will have charge will contain 1040 beds.

It is reported that an epidemic of typhus is raging in the town of Urumiah, Persia, where a Presbyterian mission is located. Nearly all the missionary staff, including Dr. Harry P. Packard of Denver, Colo., are ill, and two fatalities, one medical missionary and a woman worker, have occurred. Several hundred native victims are ill at the mission. It may be recalled that it was to this mission that 15,000 refugees fled when, in March, the Kurds swept down upon the district, killing the Christians of all races. Dr. Packard, who is in charge of the mission, recently returned from a vacation in the United States. It was at the time proposed that he be transferred to a more important mission. The Mohammedan priests and Moslem nobles of the district, many of them former patients in the hospital, protested so strongly against his removal that the plan was abandoned and it is to this friendship so widely felt for Dr. Packard, that the American missionaries attribute their safety in that critical period.

The American Red Cross is at present maintaining hospitals in every one of the countries involved in the European War, and additional hospital units will be sent as rapidly as they can be raised and equipped. The secretary of the New York State branch of the Red Cross, issued on May 23, a statement relative to its work from which may be quoted the following paragraph relative to conditions in Serbia:—

"The Serbian problem is perhaps the most serious that confronts us at the present time. Within the past ten days we have sent to Dr. Strong, the head of the Red Cross Commission in that country, nearly \$40,000 worth of supplies. These supplies included more than 250,000 pounds of sulphur and large quantities of other disinfectants, hospital equipment, tents, automobile tools and other things urgently needed in the battle being waged to rid Serbia of disease."

The greatest present need of the Red Cross is for funds, and this need is greatly increased by the recent entrance of Italy into the war.

Report from Paris on May 24 states that another American field hospital has been established at the front by the anonymous gift of \$10,000 each from three Americans. "The field hospital, in which are twenty tents, has been set up in the Bois de Boulogne. Six of the tents are of large size, being capable, if crowded, of taking care of 200 wounded men. A staff of American ambulance volunteers, among whom Columbia and Harvard Universities and Williams, Amherst and Washington State colleges are represented, has been training for tent pitching. A party of French officers witnessed with astonishment the putting up of a hospital tent complete in 15 minutes and its taking down in six minutes.

Captain Arthur W. Kipling of New York is in command of the staff. Robert M. Clay of New York is in charge of the field section, with J. C.

Hulbert second in command. R. J. Cuninghame of England, the South African lion hunter, is in charge of the tents.

The hospital will be located at a point to be selected by the French sanitary service, just outside the range of the guns."

On account of its recent long distance bombardment by the Germans, it is reported that Dunkirk has been evacuated as a hospital and supply base by the allied armies.

On May 28 the totals of the principal American relief funds for the European War reached the following amounts:—

	N. Y.	N. E.
Belgian Fund		\$259,517.97
Jewish Fund	\$674,805.22	
Red Cross Fund	494,442.78	
American Ambulance	392,363.24	
Prince of Wales	145,000.00	
Serbian Fund	65,761.97	31,647.25
Polish Fund	79,265.70	
Persian Fund	31,241.22	

BOSTON AND NEW ENGLAND.

SCARLET FEVER EPIDEMIC IN MELROSE.—The Winthrop School in Melrose, attended by 400 pupils, has been closed because of an epidemic of scarlet fever. Twenty-three cases had been reported on May 26, with one death. It is believed that an infected milk supply is the cause of the contagion.

DIVISION OF HYGIENE.—Dr. Allan J. McLaughlin, commissioner of health, has established a new department to be known as the Division of Hygiene and appointed Professor Selskar M. Gunn of the Institute of Technology and Simmons College as its chief. Some of the duties of the division will consist in directing child welfare work, public health nursing, promoting traveling exhibits, public lectures and distributing health bulletins and pamphlets.

THE DENTAL NURSE BILL.—On May 21 the House of Representatives of the Massachusetts General Court, refused to accept the report of its committee on ways and means, which advised rejection of the bill providing for the reorganization of the Massachusetts State Board of Registration in Dentistry. By a roll call vote of 130 to 84 this bill was, therefore, replaced on the legislative calendar.

PHYSICAL DEFECTS IN BOSTON SCHOOL CHILDREN.—Dr. Thomas F. Harrington, director of Hygiene in the Boston public schools, has recently rendered a report presenting the result of physical examination of Boston school children in the elementary grades. It appears that over two thousand pupils in these grades have physical defects which hinder their promotion. One-third of all pupils required to repeat grades have physical defects to which their failure may fairly be attributed. The presence of hypertrophied

tonsils and adenoids is found to be the most frequent physical cause for retardation of mental progress in the schools.

TUFTS MEDICAL ALUMNI ASSOCIATION.—The annual meeting and dinner of the Tufts Medical Alumni Association, held in Boston on May 20, under the presidency of Dr. H. A. Donnell, was attended by 60 members and guests. Addresses were made by President H. C. Bumpus, by Dr. C. F. Painter, and by Professor Charles Knowlton. The following officers were elected for the ensuing year: President, Dr. J. F. Coupal, Boston; vice presidents, Dr. I. H. Coriat, Dr. E. I. Wagner, Dr. S. E. Coppinger and Dr. W. H. Green; secretary, Dr. A. P. Cornwall; assistant secretary, Dr. E. M. Brooks; treasurer, Dr. R. B. Sprague; alumni council, Dr. E. M. Rabe, Dr. F. F. Rice, Cambridge; Dr. J. H. Mehan, Lowell; Dr. C. R. Morgan, Dr. Laura A. Hughes, Dr. W. H. White, Dr. J. W. Hinckley, Dr. E. B. Lyle, Brookline, and Dr. E. F. Sewall, Somerville.

MASSACHUSETTS COLLEGE OF PHARMACY.—The forty-seventh annual commencement exercises of the Massachusetts College of Pharmacy were held in Boston on Thursday afternoon, May 20. Degrees were awarded to a class of 38 candidates.

BROCKTON DEPARTMENT OF PUBLIC HEALTH.—The report of the health department of the city of Brockton, Mass., for the year 1914, states that the birth rate was 23.68 and the death rate 11.61. During the year representatives from the Public Health Service in Washington, D.C., made a survey of factory conditions and a study of tuberculosis as a disease of occupation. The department of child hygiene, bureau of commerce and labor, made a survey of the city in regard to infant mortality, on account of the unusually low death rate which the city enjoys. During the last 15 years it has averaged 2.8 per thousand inhabitants as compared with 3.7 for Massachusetts as a whole. Two milk stations were opened during the summer months and cared for 200 babies. As causes of death in the city during the past year, diseases of the heart and arteries rank first, pneumonia second, cancer and tuberculosis fifth and sixth respectively.

BOSTON MILK AND BABY HYGIENE ASSOCIATION.—It is announced that the Boston Milk and Baby Hygiene Association has recently received from the executor of the late Julia M. Moseley of Newburyport, Mass., an endowment fund of \$10,000 given by Mrs. Moseley to be known as the Caroline Louise Moseley Fund, the income to be used in the work of the Association.

BOSTON CITY HOSPITAL TRAINING SCHOOL FOR NURSES.—The graduating exercises of the Training School for Nurses of the Boston City Hospital were held on Friday, May 28. Diplomas were awarded to 40 nurses.

Massachusetts Medical Society.

PROGRAM OF THE 134TH ANNIVERSARY.

The 134th anniversary of the Massachusetts Medical Society will be observed on Tuesday and Wednesday of next week, June 8 and 9 in Boston. A preliminary program of the exercises was published in the issue of the JOURNAL for May 13. Following is the entire body of the program of exercises on both days:—

GENERAL INFORMATION.

A BUREAU OF INFORMATION will be maintained by the Committee of Arrangements during Tuesday and Wednesday in the lobby of the Copley-Plaza Hotel, the headquarters of the Society during the Annual Meeting.

THE ANNUAL DINNER AND ALL GENERAL AND SECTION MEETINGS (with the exception of the combined meeting of the Sections of Medicine and Surgery on Wednesday afternoon) will be held as in 1913 and 1914 at the Copley-Plaza Hotel. During both days of the meeting the facilities of the hotel will be at the disposal of the members of the Society, and parking space for automobiles, with supervision, will be provided. By arrangement with the management, rooms may be secured at a reduced rate by fellows of the Society desiring to spend Tuesday or Wednesday night in Boston.

CLINICS AND DEMONSTRATIONS will be held at the various hospitals on Tuesday morning and will be related as far as possible to subjects to be discussed during the meeting.

The Boston Medical Library, 8 The Fenway, will be open for the inspection and use of the fellows during the days of the meetings.

The Harvard Medical School, 210 Longwood Avenue, and the Tufts College Medical School, 416 Huntington Avenue, will be open for inspection by the fellows both Tuesday and Wednesday.

JUNE 8, 1915.

TUESDAY MORNING.

CLINICS AT THE VARIOUS HOSPITALS.

AT THE BOSTON CITY HOSPITAL.

Demonstrations will be presented in the Surgical Amphitheatre, beginning at ten o'clock, as follows:

1. Pericarditis.—Drs. Sears and Palfrey.
2. Diagnosis of Chest Conditions.—Dr. Ames.
3. Heart Cases.—Dr. Phipps.
4. Transfusion.—Dr. Kimpton.
5. Specimens of Acute Unilateral Hematogenous Infection of the Kidney.
Diverticulæ of the Bladder.
Cyst of the Prostate. } Dr. Cunningham.
6. Tendon Plastics.
Bilateral Empyema. } Drs. Lund and Loder.
7. Modern Anesthetic Methods. Dr. F. L. Richardson.
8. A Series of Gross Specimens of Lesion of the Liver.—Dr. L. U. Gardner.
9. Renal and Ureteral Calculi.—Dr. Blinney.
10. Diagnosis of Early Syphilis of the Nervous System.—Dr. Coriat.
11. Salvarsanized Serum Therapy in Neurosyphilis.—Dr. Sanborn.

Throughout the morning, the hospital will welcome physicians in all its Departments. The schedule for the day is as follows:

- 9.30 A.M. General surgical operations and ward visits by Drs. Faulkner, Hubbard, Crandon, Scannell, Cunningham and Loder. First, second and third operating rooms.
- 9.30 A.M. Genito-urinary operations and ward visit by Drs. Thorndike and Binney. Large operating room.
- 9.30 A.M. Aural operations and ward visit. Dr. Borden. Large operating room.
- 9.30 A.M. Gynecological operations. Drs. Young and Mason. Ward "S" operating room.
- 9.30 TO 12.00 Roentgenological Demonstration with especial reference to pulmonary and gastro-intestinal diseases, by Dr. Ellsworth, X-ray department.
- 9.30 TO 12.00 Pathological, bacteriological and serological diagnostic methods. Dr. Mallory, Pathological laboratory.
- 10.00 A.M. Medical ward visits by Drs. Sears, Ames, Robey, Larrabee, Palfrey and Phipps.

AT THE MASSACHUSETTS GENERAL HOSPITAL.

(The schedule will be carried out at the times given irrespective of attendance.)

- 10.00 A.M. Nerve Department. An Outline of an Intensive Study of Epilepsy.
- 10.10 A.M. Children's Medical Department. Tonsillectomy in Chorea.
- 10.20 A.M. Dr. E. G. Brackett. Cases of Knee-arthrotomy by Median Patellar Incision.
- 10.30 A.M. Dr. C. M. Smith. The Diagnosis of the Primary Lesion of Syphilis.
- 10.40 A.M. Dr. H. Cabot. Carcinoma of the Bladder.
- 10.50 A.M. Dr. G. W. Holmes. The Results of Roentgenoscopic Examination of Gastro-Intestinal Cases During the Past Year.
- 11.00 A.M. Dr. C. L. Scudder. Surgical Treatment of Non-Pyloric Gastric Ulcer.
- 11.10 A.M. Drs. O. Folin and W. Denis. The Occurrence of Phenols and Phenol Derivatives in the Urine.
- 11.20 A.M. Dr. H. Williams. Obstruction of the Common Bile Duct.
- 11.30 A.M. Dr. R. I. Lee. Experimental Purpura Hemorrhagica.
- 11.40 A.M. Dr. D. F. Jones. Treatment of Inoperable Carcinoma of the Rectum.
- 11.50 A.M. Dr. C. A. Porter. Graves' Disease.

Selected operations will be performed in the smaller operating rooms, 10 to 12 A.M., and in the surgical amphitheatre, 12 to 1, by members of the general surgical, genito-urinary and orthopedic staffs.

- 10.00 A.M. Neurological ward visit. Dr. Fairbanks.
- 10.00 TO 12.00 Salvarsanized Serum Treatment of Tabes. Dr. Sanborn.
- 10.00 TO 12.00 Second accident room.
- 10.00 TO 12.00 Cystoscopic Examination and Renal Functional Tests. Dr. Cunningham.
- Cystoscopic room.

Physicians interested in the medical, neurological and gynecological work will find it convenient to enter the hospital by way of the medical office; those interested in the general, genito-urinary or aural surgery and in the special demonstrations should enter by the surgical office. Operations for the day will be posted at the superintendent's office Monday morning, and in the amphitheatre Monday evening.

AT THE PETER BENT BRIGHAM HOSPITAL.

- 10.00 TO 12.30 Exhibition of Cases, with demonstrations and operative clinic by members of the Medical and Surgical Staffs of the Hospital. Detailed program will be found at the Hospital on the morning of the meeting.

AT THE CARNEY HOSPITAL.

There will be a Surgical, a Gynecological and an Orthopedic clinic in the operating rooms, beginning at 9.30 A.M. The Medical Service will make a ward visit.

AT THE CHILDREN'S HOSPITAL.

Medical Service. Dr. John Lovett Morse will make a ward visit and demonstrate interesting cases at 10.30 A.M. *Surgical Service.* Operations will be performed, interesting cases demonstrated in the wards, and end results in cases including empyema will be shown. *Orthopedic Service.* A ward visit with demonstration of interesting cases of bone tuberculosis and infantile paralysis will be made at 10 A.M., and there will be a demonstration of cases and methods of treatment in infantile paralysis, and operations will be performed in the amphitheatre at 11 o'clock A.M.

AT THE INFANTS' HOSPITAL.

A ward visit will be made by members of the Staff at 10.30 A.M.

AT THE FREE HOSPITAL FOR WOMEN.

Gynecological Operations will be performed by the Staff from 7.15 A.M. to 1 P.M.

ANNUAL MEETING OF THE SUPERVISORS.

FOYER, COPLEY-PLAZA HOTEL.

11.30 O'CLOCK.

JUNE 8.

TUESDAY NOON.

ANNUAL MEETING OF THE COUNCIL.

FOYER, COPLEY-PLAZA HOTEL.

12 O'CLOCK.

JUNE 8.

TUESDAY AFTERNOON.

MEETING OF THE SECTION ON MEDICINE.

FOYER, COPLEY-PLAZA HOTEL.

2.30 O'CLOCK.

Officers of the Section of Medicine:

DR. ELLIOT P. JOSLIN, Boston, *Chairman*.
DR. WALTER W. PALMER, Boston, *Secretary*.

SYMPOSIUM ON HEART DISEASE.

1. The Use of Digitalis in the Various Forms of Cardiac Arrhythmias.—Dr. Henry A. Christian, Boston.
2. The Relation of the Abnormal Heart Beat to Prognosis.—Dr. Paul D. White, Boston.
3. Treatment of Heart Disease.—Dr. F. C. Shattuck, Boston.

Discussion:—Dr. John Sproull, Haverhill; Dr. Francis W. Palfrey, Boston; Dr. J. H. Pratt, Boston.

JUNE 8.

TUESDAY AFTERNOON.

MEETING OF THE SECTION OF SURGERY.
STATE DINING ROOM, COPLEY-PLAZA HOTEL.
2.30 O'CLOCK.

Officers of the Section of Surgery:

DR. JOHN BAPST BLAKE, Boston, *Chairman*.
DR. EDWARD P. RICHARDSON, Boston, *Secretary*.

1. Demonstration of a method by which fragments of needles lodged in tissues near the surface of the body may be localized by means of magnetism.—Dr. George H. Monks, Boston.
2. Acute Perforations of Ulcers of the Stomach and Duodenum.—Dr. W. E. Faulkner and Dr. I. J. Walker, Boston.
3. Traumatic Perforation of the Duodenum.—Dr. David Cheever, Jr., Boston.
4. Cholelithiasis: An Argument for Early Operation.—Dr. Joshua C. Hubbard, Boston.
5. A Brief Consideration of Acute Pancreatitis, with Case Reports.—Dr. C. E. Durant, Haverhill.

Discussion:—Dr. P. E. Truesdale, Fall River; Dr. Hugh Williams, Boston; Dr. D. F. Jones, Boston; Dr. Hardy Phippen, Salem.

JUNE 8.

TUESDAY AFTERNOON.

BALLROOM, COPLEY-PLAZA HOTEL.
2.30 O'CLOCK.

Officers of the Section of Tuberculosis:

DR. ALBERT C. GETCHELL, Worcester, *Chairman*.
DR. JOHN B. HAWES, 2ND, Boston, *Secretary*.

1. Non-tuberculous Cases at the State Sanatoria.—Dr. Elliott Washburn, Superintendent, Rutland State Sanatorium.

Discussion:—Dr. E. A. Locke, Boston; Dr. I. J. Clarke, Haverhill; Dr. C. C. MacCorison, Superintendent, North Reading State Sanatorium; Dr. Charles E. Perry, Superintendent, Hampshire County Sanatorium.

2. Errors in Diagnosis in Chronic Diseases of the Lungs.—Dr. John B. Hawes, 2nd, Boston.

Discussion:—Dr. Allan G. Rice, Springfield; Dr. John H. Gifford, Fall River; Dr. Frederick T. Lord, Boston; Dr. H. C. Clapp, Boston.

3. What Constitutes Tuberculosis in Childhood.—Dr. John Lovett Morse, Boston.

Discussion:—Dr. Walter C. Bailey, Boston; Dr. Cleveland Floyd, Boston; Dr. F. B. Talbot, Boston; Dr. H. D. Chadwick, Superintendent, Westfield State Sanatorium.

JUNE 8.

TUESDAY EVENING.

THE SHATTUCK LECTURE.
FOYER, COPLEY-PLAZA HOTEL.
8 O'CLOCK.

By DR. JOEL E. GOLDSWORTHY, Boston.

Subject: "An Anatomic and Mechanistic Conception of Disease."

At the close of the lecture there will be an Informal Reception to the President; Music by the Boston Festival Orchestra and Mr. Alfred Denghausen, Baritone; Refreshments.

JUNE 9, 1915.

WEDNESDAY MORNING.

ONE HUNDRED AND THIRTY-FOURTH ANNIVERSARY.
FOYER, COPLEY-PLAZA HOTEL.
9.30 O'CLOCK.

Business of the Annual Meeting.

Program arranged by the Sub Committee on Scientific Papers of the Committee on Publications and Scientific Papers, Dr. James S. Stone, Boston, and Dr. Frederick T. Lord, Boston.

The papers will be devoted to the following topics, viewed from the standpoint of Public Health and Preventive Medicine. Each speaker will be limited to ten minutes.

1. The Work and Aims of the State Department of Health.—Dr. Allan J. McLaughlin, Boston.
2. Pneumonia.—Dr. Frederic T. Lord, Boston.
3. Infant Mortality.—Dr. John Lovett Morse, Boston.
4. Typhoid Fever.—Dr. M. W. Richardson, Jamaica Plain.
5. Preventable Heart Disease.—Dr. Roger I. Lee, Cambridge.
6. Tuberculosis.—Dr. Arthur K. Stone, Boston.
7. Syphilis.—Dr. Abner Post, Boston.
8. Contagious Diseases.—Dr. Eugene R. Kelley, Boston.
9. Cancer.—Dr. Edward Reynolds, Boston.

TWELVE O'CLOCK, NOON.

THE ANNUAL DISCOURSE WILL BE DELIVERED BY
DR. EVERETT A. BATES, SPRINGFIELD.

Subject: "Some Perplexities in Modern Medicine."

JUNE 9, 1915.

WEDNESDAY AFTERNOON.

COMBINED MEETING OF THE SECTIONS OF MEDICINE AND SURGERY.

SURGICAL AMPHITHEATRE, BOSTON CITY HOSPITAL,
HARRISON AVENUE.

2.30 O'CLOCK.

Chairmen: DR. ELLIOT P. JOSLIN, Boston; DR. JOHN BAPST BLAKE, Boston.

Secretary: DR. WALTER W. PALMER, Boston.

SYMPOSIUM ON EMPYEMA.

1. The Medical Aspects of Empyema and Pulmonary Abscess.—Dr. F. T. Lord, Boston.
2. The Recognition of Pleural Disorders by X rays, with Especial Reference to Empyema.—Dr. Percy Brown, Boston.
3. Pneumo Dynamics of the Treatment of Empyema.—Dr. F. C. Cotton, Boston.
4. The Surgical Treatment of Chronic Empyema.—Dr. F. B. Lund, Boston.
5. Lung Abscess and Bronchiectasis from a Surgical Point of View; End Results of Acute and Chronic Empyema.—Dr. Wyman Whittemore, Boston.

Discussion:—Dr. George G. Sears, Boston; Dr. John Homans, Boston; Dr. James S. Stone, Boston; Dr. Frank L. Richardson, Boston.

JUNE 9, 1915.
WEDNESDAY EVENING.

7 O'CLOCK.

The ANNUAL DINNER will be served in the BALL-ROOM OF THE COPLEY-PLAZA HOTEL, promptly at 7 o'clock. No dress suits.

DINNER TICKETS.

Tickets for the Annual Dinner at one dollar apiece may be obtained at the Bureau of Information during the two days of the meeting by those fellows whose current dues are paid up.

NOMINATING COMMITTEE.

Following is the nominating committee elected by the District Societies at their annual meetings in April and May, 1915, to nominate officers and orator at the annual meeting of the Council, June 8, 1915:

	Principal	Alternate
BARNSTABLE	E. E. HAWES	C. W. MILLIKEN
BERKSHIRE	L. A. JONES	J. H. RILEY
BRISTOL NORTH	F. A. HUBBARD	R. D. DEAN
BRISTOL SOUTH	H. G. WILBUR	A. H. MANDELL
ESSEX NORTH	F. W. SNOW	R. V. BAKETEL
ESSEX SOUTH	J. F. O'SHEA	BUTLER METZGER
FRANKLIN	G. P. TWITCHELL	
HAMPDEN	S. A. MAHONEY	J. M. BIRNIE
HAMPSHIRE	F. H. SMITH	J. S. HITCHCOCK
MIDDLESEX EAST	C. J. ALLEN	W. H. KELLEHER
MIDDLESEX NORTH	T. G. MCGANNON	G. O. LAVALLEE
MIDDLESEX SOUTH	E. H. STEVENS	C. E. PRIOR
NORFOLK	T. J. MURPHY	A. N. BROUGHTON
NORFOLK SOUTH	J. A. GORDON	C. S. ADAMS
PLYMOUTH	A. E. PAINE	F. G. WHEATLEY
SUFFOLK	J. J. MINOT	G. W. W. BREWSTER
WORCESTER	DAVID HARROWER	R. W. GREENE
WORCESTER NORTH	E. A. SAWYER	A. P. MASON

Obituary.

MICHAEL FREEBERN GAVIN, M.D.

DR. MICHAEL FREEBERN GAVIN died at his home in South Boston, May 20, 1915, after an illness of eight years. He was born in Rosecommon, Ireland, May 12, 1844, coming to this country as a young man and entering the Harvard Medical School, from which he was graduated with the class of 1864. Dr. Gavin was among the group of house officers that was the first to graduate from the Boston City Hospital, and later in life he was visiting surgeon to this institution for many years, being consulting surgeon at the time of his death. During the Civil War he served as assistant surgeon to the 57th Massachusetts Infantry and at its close settled in practice in South Boston. Studying abroad in 1865 and 1866 he became a Fellow of the Royal College of Surgeons of Ireland. He was a Fellow of the Massachusetts Medical Society, member of the American Medical Association, member Boston Medical Library, the Boston So-

ciety for Medical Improvement and the British Medical Association; consulting surgeon, Carney and St. Elizabeth's Hospitals and St. Mary's Infant Asylum. At one time, from 1878 to 1884, Dr. Gavin was a trustee of the Boston City Hospital. He was also a director of the Union Institution for Savings and of the Mattapan Deposit and Trust Company. From 1888 to 1891 he was a teacher of clinical surgery in the Boston Polyclinic. During his long years of service at the City, Carney and St. Elizabeth's Hospitals he was known to a large number of house officers, to whom he was most generous, and to the visiting staffs as a surgeon of conservative judgment and a kindly, considerate and courteous gentleman. He is survived by a widow, a daughter and one son.

Miscellany.

AFTERMATH OF THE CLEAN MILK BILL.

In last week's issue of the JOURNAL we commented editorially on the governor's veto of the Labor Clean Milk bill and in another column published the text of his veto message. In the succeeding column of the present issue of the JOURNAL we publish a further communication bearing on this important subject. In this conjunction it seems desirable also to reprint in part the following statement issued by the council for the Massachusetts Milk Consumers' Association in reply to various statements made in the governor's veto message.

"The laws of 35 other states give the consumers more protection than is given in Massachusetts. This legislation originated with Dr. Charles Harrington when he was secretary of the state board of health.

"There are some very brilliant exceptions, but in general it may be said that the local boards of health fail to do their 'duty under the present laws,' and they do not 'vigorously exercise' the ample powers which they do in fact possess. A large number of local boards have no physicians or trained men connected with them.

"Only 97 out of 354 cities and towns even have an official called a milk inspector. Very few of these milk inspectors inspect dairies or do more than analyze milk for fats and solids. Only three or four local boards pay any attention to the long haul, out-of-state dairies.

"The answers to a questionnaire sent out by the Milk and Baby Hygiene Association prove conclusively that very few local boards are enforcing the acts of 1914, chapter 744, so largely relied upon by the governor in his message. When the board of health of Winthrop started to enforce the act of 1914, the first contractor

sent in a list of 1500 dairies, chiefly out of state, which it would be their duty to inspect. As Winthrop received only a few drops of milk from each of these dairies, and as most of the milk went to many other places in the state, they dropped the matter immediately on the ground that this work the state department of health ought to do in order to save needless duplication, and it was for this reason that the Winthrop board of health supported the Clean Milk bill.

"The Labor Clean Milk bill deals very leniently with producers. No man who is willing to 'clean up' when requested to do so, or possibly to put in a window or to replace a rotten floor, would come within its terms. The master of the state grange, Representative E. K. Chapman, stated that he was satisfied with it when the amendment giving producers 20 days in which to remove objectionable features was added. He stated on the house floor that it would not affect more than 25 or 30 producers in the state of Massachusetts.

"Instead of creating discrimination, it tends to remove the discrimination against Massachusetts producers. The bill applies to milk produced outside of the state under insanitary conditions.

"If Mayor Curley's \$35,000 bill for the exclusive inspection of out-of-state dairies, which was killed by the grangers in the Legislature, had been passed, it would, in conjunction with this bill, have completely eliminated the unfair discrimination against Massachusetts producers.

"Perhaps the most astonishing thing in the message is that the bill 'will not improve the quality of our milk supply one iota, since it deals only with the conditions of production without any attention to the actual quality of the product.' I think it will be generally conceded that improving the conditions of production will improve the quality of the product.

"The purpose of the bill is to remove the causes of dirty milk by keeping the dirt out of the milk, in the first instance, as far as possible.

"We approve of milk tests in connection with dairy inspection, but realize that in most instances the milk is consumed long before the result of the milk test can be known."

Correspondence.

AFTERMATH OF THE CLEAN MILK BILL.

CANTON, MASS., May 22, 1915.

Mr. Editor:

Now that the Clean Milk Bill, after being slowly dismembered, has been finally relegated to the scrap-heap (a fate which the writer thinks it justly deserved), is it not the time to investigate with a view to learning what legislation our Commissioner of Health wishes enacted in order to facilitate his work? If we put the same amount of energy toward gaining this as has been expended in endeavoring to push

through some sort of milk bill the results probably will be more satisfactory.

It seems to the writer that milk production and distribution is the affair of the locality in which that milk is consumed. The product is what the consumer is interested in. Make the product come up to a standard of purity and the methods will look after themselves. Now the product, whether produced in or out of the state, by good or poor methods, when it reaches a given community should be fit for consumption. If it is not fit for use its distribution should be prohibited. Dairies whose milk has been refused will soon remedy conditions themselves, a thing which they will never do if you inspect them from now until the end of the world. Dairymen are tired of inspections and will rarely obey instructions given by an inspector. Now if you shut off his means of disposing of his milk because it is not clean, not fit for food, it will take him just twenty-four hours to correct the mistake or take means to find out where his trouble is.

This milk question is a matter which must be settled by each locality for itself. If a locality doesn't wish to drink dirty milk it will refuse to do so. In that case it doesn't need anyone to prescribe for it. If a locality doesn't care what kind of milk it drinks it will soon find it gets all the poor milk, which in itself will be the very thing needed to bring it to the place where it, too, will demand clean milk. The amount of dirty milk consumed in a given city or town depends on that city or town, and indirectly on its health officials, and you can't shift the responsibility to any state department of health.

As I said in a previous communication, I believe that the State Department of Health should have authority over local boards, but this should be given to it in some far-reaching comprehensive manner, and not in the matter of milk production alone.

Respectfully yours,

DEAN S. LUCE, M.D.

COMPULSORY TREATMENT FOR SYPHILIS.

DALLAS, TEX., May 17, 1915.

Mr. Editor:

So much good has come from the Harrison Narcotic Act, it has occurred to me much could be accomplished by a law providing for compulsory treatment for syphilis. All must confess our present system in combating the propagation of the disease, is a failure. Our health boards, hospitals, and private individuals, have spent thousands of dollars in combating tuberculosis; but what has been accomplished in syphilis? We have our insane asylums rapidly filling up with cases of general paralysis, and other forms of mental disease, caused by syphilis. About 80% of all the cases of blindness in our asylums are caused from venereal diseases. In our large cities, there are undoubtedly three cases of syphilis to one of tuberculosis. Yet this plague is hidden from the eye of the casual observer. Indeed there may be few symptoms, or even none, detected, even after a careful medical examination, and the person may still be in the infectious stage. Hundreds, and I may say thousands, of men and women, eat daily in restaurants, and boarding houses, with mucous patches in their mouths, and the same spoons and forks used by them, are handed to other persons the next meal, the only disinfectant being some slightly warmed dishwater.

If we are able to enforce the law of compulsory vaccination; if we can isolate persons with smallpox, bubonic plague, yellow fever and other infectious diseases, why not have a law for compulsory treatment for syphilis? We now have the Wassermann test, and are able to detect easily an infectious case, even without observable symptoms. The only difficulty would be in catching our patient. In order to get a practical law on the statute books, we should not attempt anything too drastic at first. We should have to contend with a suspicious and unenlightened public; and with equally ignorant and obstinate law-

makers. Did not vaccination meet with opposition in its early days?

If our health boards would give the matter careful consideration, and present the true facts before our city authorities, they could, no doubt, secure the enactment of a law compelling all persons convicted of vagrancy in our police courts, to submit to the Wassermann test. Vagrants could either be detained in the city jails, or released on bond, to appear in court in ten or fifteen days. If a positive reaction were found, they could be turned over to a board of health for compulsory treatment. They should be placed in a hospital, and their clothing taken away from them and nightgowns substituted to prevent them from running away, a procedure now generally followed with "dope fiends." After the public had been shown that no less than 80% of all vagrants, both men and women, are infectious syphilitics, the law could be extended to apply to all convicted criminals, and later made to include all persons who became a public charge. In this way thousands of syphilitics could be rendered non-infectious. After many years of faithful teaching, the general public might be brought to submit to a general blood test, say once in one or two years. If every person in the United States, between the ages of 16 and 60 should submit to a blood test once a year, the disease would soon be wiped out. The cost of an organized system of blood examination and treatment would be less than caring for the chronic syphilitics and their descendants: and the relief of suffering would be inestimable. Who would not give a few drops of his blood once a year to assist in blotting out such a terrible disease?

Very truly yours,

DAVID G. HALL, M.D.

The following is an extract from a letter from Dr. George W. Crile of Cleveland:

"When I was in Belgium I received first-hand information from a number of Belgian physicians concerning their plight. They are indeed in dire need and there seems to be no way by which this need can be overcome until their land is restored to them again. The free masonry of the medical profession so binds

all medical men together that it seems to me that no appeal to doctors for the aid of their associates in Belgium can be in vain. We should all realize also that no single appeal can satisfy what is going to be a long continued need, that we must give now, later again, and still later and so answer repeated appeals until later conditions may restore to the Belgians the wherewithal to aid themselves."

SOCIETY NOTICE.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The annual meeting will be held at the Copley-Plaza Hotel, Boston, on Tuesday, June 8, 1915, at 2 o'clock.

Preceding the meeting, the annual lunch will be served in an adjoining room.

Annual reports and election of officers.

The following papers will be read and discussed:

1. "Chemical Tests for Cyanide Poisoning," Dr. William F. Whitney, of Harvard Medical School.

2. "The Disposition of Property Found on or about the Body," Dr. Fred E. Jones, Medical Examiner, of Quincy.

3. "Accidental Death from a Stray Shot from Unusual Distance," Dr. Charles W. Milliken, M.D., Medical Examiner, of Barnstable.

OLIVER H. HOWE, M.D.,
Recording Secretary.

NOTICE.

HARVARD MEDICAL ALUMNI ASSOCIATION.

An informal table d'hôte luncheon will be held by the Harvard Medical Alumni Association on June 23 at the University Club in San Francisco. Dr. William P. Lucas of the University of California Medical School and Mr. William Thomas, president of the San Francisco Harvard Club will be in charge.

APPOINTMENTS.

Dr. Edward C. Rosenow, of the Memorial Institute of Infectious Diseases, Chicago, has recently been appointed to the position of chief of bacteriologic research, Mayo Foundation, Rochester, Minn.

Dr. J. Alexander Murray has been appointed general superintendent of the Imperial Cancer Research Fund and director of the laboratories to succeed Dr. E. F. Bashford.

Dr. Lentz, director of the Prussian imperial health office, has been appointed the reporting councilor in the medical department of the ministry of the interior. He succeeds Dr. Abel who has been transferred to the Institute of Hygiene at Jena.

Dr. Thomas Ordway, Harvard Medical School, has accepted the deanship of the Albany Medical College. Dr. Ordway was formerly professor of pathology at that institution.

Dr. Samuel G. Dixon has been reappointed as Commissioner of Health of the Commonwealth of Pennsylvania.

RECENT DEATHS.

DR. HENRY WALTON WOOD, a Fellow of The Massachusetts Medical Society, died at Philadelphia, Penn., Jan. 12, aged 35 years, of tuberculosis.

DR. JOHN JOSEPH HECTOR MCALLESTER, a Fellow of The Massachusetts Medical Society, died of nephritis at New Bedford, Mass., April 16, aged 37 years.

ANNUAL DISCOURSE.

NOTE.—At an adjourned meeting of the Massachusetts Medical Society held Oct. 3, 1860, it was

Resolved, "That The Massachusetts Medical Society hereby declares that it does not consider itself as having endorsed or censured the opinions in former published Annual Discourses, nor will it hold itself responsible for any opinions or sentiments advanced in any future similar discourses."

Resolved, "That the Committee on Publications be directed to print a statement to that effect at the commencement of each Annual Discourse which may hereafter be published."

SOME PERPLEXITIES IN MODERN MEDICINE.*

By EVERETT A. BATES, M.D., SPRINGFIELD, MASS.

It is proper and appropriate that, we, members of the Massachusetts Medical Society, should upon occasions like this turn our thoughts to some subject whose consideration may illumine our path or encourage us if appalled by the magnitude of professional detail.

More than a hundred addresses have been delivered since it became the custom of the Massachusetts Medical Society to choose from its members an orator for its annual discourse.

These discourses have embodied subjects pertinent to the time, as the wave of medical progress tossed into view some new thought from out the depths of unknown problems; and each orator has given his best efforts, and has been stimulated to this effort by the example of each individual among a long list of physicians eminent

* The Annual Discourse delivered before The Massachusetts Medical Society at Boston, June 9, 1915.

in teaching, devoted to their work, and serious minded in their duty.

These splendid examples I cannot hope to emulate nor can I expect even a modest approach to their successes; but I deeply appreciate the honor you have given me, and my desire is to prove a not unworthy representative of my brethren of the Connecticut valley.

In the vast library of medical literature of today it would seem that no phase of scientific investigation as applied to medical progress is left untouched; this great volume of knowledge is a startling testimonial of the restless activity of minds working along a multitude of different radiants toward a common goal or centre. It is a mass of material that contains an abundance of folly and error as well as an abundance of worth; and its final analysis and the summation of facts that have stood the test of dispute and counter dispute constitutes our present day knowledge of medical sciences and has provided the basis of its application to the prevention and relief of diseases. We have not been alone in our far wanderings, haltings and uncertainties; for every progressive thought, as mirrored in the picture of scientific accuracy as we see it today, is the wonderful composite of a myriad of sittings and exposures; and the thought of the future portrays a strenuous individualism in the contemplation of which the mind wearies.

The history of medicine itself is the history of a workshop in which different working units have patiently and with painful effort constructed a system which we call today the Science of Medicine and Surgery.

That which was gross and invisible in the hu-

man body naturally first claimed the attention, and gave to anatomy its right to be considered the fundamental and original medical science; the possibilities that it gave for exact knowledge more especially when the microscope revealed the minute structure, from the embryo to maturity, has enhanced its value to the student in his thought of that which is best adapted to the practical side of his coming vocation; to be a prosector in a medical school twenty-five years ago was the acme of his ambitious elementary years; and the field of surgery must ever prove of tempting glamor. Naturally the function of a part went with its structure so that physiology followed hand in hand with anatomy its tedious course of progress, getting only now and then through the centuries the impulse of the master mind of a Galen and Harvey, but finally emerging as an intricate and bewildering science, and one which, intensely essential in its elementary values, is, through its advances in the past decade in the chemistry of digestion, nutrition and metabolism, quite beyond the absorbing capacity of the busy physician of an earlier training.

Pathology, the beginning of the science upon which the practice of medicine is, or should be, based, must necessarily arise when the early investigators of the human body began to find in their dissection certain variations from the organs as commonly noted; but not till fifty-five years ago did the great Virchow proclaim his cellular pathology, demonstrating that all bodies are made up of cells, and that each cell has a unity and purpose of its own,—thus, through the nature of normal function, showing the way to physiologic and pathologic experimentation. Finally, the microscope in the hands of a Pasteur and a Koch gave bacteriology to the world, the last and youngest of all the medical sciences, and completed the link in a chain of discoveries that are slowly solving the mysteries of life and that which makes for better living, better work, better rewards,—the healthy human body; for the ultimate perfection of the human race is the dream of the soaring fancies. And out of the limitless researches into these correlated sciences has come practical medicine as we see it today; an achievement of which we are justly proud, and upon which we love to dwell in words of praise; its scope is boundless, for by it we would preserve the normal through the prevention and control of all agencies that are destructive to it,—impressing legislative and federal control when necessary to better accomplish the result, we would discover by painstaking inquiry or by an elaboration of technical methods the earliest departure from this individual normal, and so provide in return an extension of its economic value; we would attempt to restore partially or wholly the person accidentally the victim of infection and trauma, or to reconstruct an anatomical or remove a pathological variation. In truth there is no region which the fancy does not penetrate in the ambitious flight of the vo-

taries of our profession, comprising a large number of experimentalists, teachers, writers, specialists, along with workers in the broad field of medicine and in its relation to the social status. A contemplation of the amount of knowledge that even a moderate acquaintance with these systematized masses of medical learning must entail upon the future student and practitioner is startling, for it intimates a degree of technical procedure and exactness that will not become any less impressive as the decades pass; and it implies that the solution of the problem of the office or the bedside or the hospital will be undertaken with an increasing scientific accuracy and precision and that it will require an ever renewed relationship on the part of the clinician with the medical scientist and his newest discoveries. The standard must constantly, although rather slowly to some of our impatient educators, advance, and the standard bearers must partake more and more of this advance in knowledge among the leaders. It is a self-evident conclusion. The chasm of ignorance thus quickly bridged in a comparatively few years is discerned by this rapid review of the history of medical growth.

Before the discovery of the great principles which lie at the bottom of our present day enlightenment, which we call scientific medicine, there existed for centuries a turmoil of contentions—a Babel of conjecture—theories varying from dogmatism to skepticism, until “confusion grew the worse confounded;” from these questionable methods, opinions and practices, many minds finally sought refuge in the simple thought of experience based upon observation as the only rational course in practice. Although empiricism was founded on speculation, Bacon, its ardent advocate in the seventeenth century, would seem to have given it the right to be considered the forerunner of our present scientific aims, when he said, “*vera scire est per causas scire*,”—to know truly, is to know through cause; and yet up to a half century ago so little had been gained by this early scientific thought that there existed only warring “schools” and “isms,” affording the defenders of each much material for discussion, but no rational, enduring and exact procedure governing health and disease.

Germany seemed first to learn the lesson that arose from the natural evolution of the medical sciences and became a power in the medical world by her painstaking application to clinical medicine, of her exact and detailed methods of investigation. It is the same impetus that has recently startled the world. A critic has said, “It is the evolution that means the survival of the fittest and the destruction of the unfit: and it places sympathy with the weak virtues as a weakness itself.” It is the philosophy of Nietzsche that “might is the ultimate proof of right.” “Get everything you have the strength to get.” To quote Charles Francis Adams, “It is the absolute negation of everything in the past which

has tended to the elevation of mankind." It is a return to the primeval law of the strongest; it has raised that much-used and misused word "efficiency" to the center of the color standard and to it everything else is subordinated.

There would seem to be a parallelism in this militaristic philosophy when applied to any conflict which reduces its methods to an exact science, and interprets its duty in terms of modern thought as one bereft of romance or any other human elements that might detract from scientific efficiency. We know there can be no finality in our work, but it is self-evident that by clinging too closely to the present day thought of scientific accuracy, the medical profession will have lost the splendid worth of cultivated or even random observation, so valuable a part of the equipment of our predecessors. Nothing really revolutionary ever occurs, and progress is more often by slow development.

Over medication in medicine received its first blow when from simple observation it was seen that many diseases ran a definite course, self limiting in time, irrespective of treatment; later, bacteriology so clearly defined the cyclic life of certain infectious organisms and the self destruction of others at the hands of nature's protecting and assisting processes, that the old faith in the cure of disease by some drastic method gave way finally to a period of therapeutic skepticism and little if any medication. Not that these days of waning confidence in drugs are the proof of their lost efficiency; no such conclusion can sanely be reached; but fortunately most of the old zeal and confidence in the utility of drugs has been brought to a safer and more practical ground, based on the more scientific reasoning of experimental pathology and pharmacology. Many of us have not forgotten the axiom of a wise clinician and practitioner.—"Never use a drug unless you are sure it is indicated, and if you do use it, use it fearlessly, to the relief of the symptom for which it is given, or to the physiological action of the drug." Such a procedure is wisely rational and implies a method based upon avoidance of medication without reasonable evidence in its favor; and requires in addition an exact knowledge of drug action, in order that a harmful result may be recognized as promptly as a beneficial one.

Long continued usage, however, has given a sanction to medication that cannot be completely overcome by the known fallacy of *post hoc ergo propter hoc*; and the exactness of our present-day science does not readily dispel what may be accounted intolerant empiricism. The iniquitous practice of bleeding may upon occasions today be condoned; the successful use of Peruvian bark was an established fact several hundred years before science had discovered the reason. Long employed customs won in many instances the right to permanent recognition, where nothing but tradition, based on ancient experience, could satisfy the claim. To walk abroad after

nightfall was to invite yellow fever; to smoke in its presence was a "charm" to your immunity,—truths nearly as self evident two centuries ago as now. So that although causation may now be the only true key to the therapeutic solution of a problem, it may still be a not altogether foolish conservatism that leads the well balanced mind to return *si opus sit* to some traditional thought or practice; for the absence of a scientific reason might cause inaction in treatment to the detriment of the patient; and while a credulous following of methods and the practice of the instructors with whom the student came in contact during the days of his medical education is to be deprecated as having its limitation, it may be stated that the true attitude must be,—respect for the past, and the ideas of our predecessors, even though greatly limited and modified. "There were great men before Agamemnon."

The disillusionment that has so completely changed the thought in medication is also apparent in the surgical field. Modern surgery has been made possible by the discovery of agents that removed the two great terrors that held it in leash,—conscious pain and sepsis. The natural result of the release of such early restrictions was evidenced in the swing of the pendulum to the extreme of its arc, and scientific ardor took the place of judgment; the earlier operations of necessity or expediency becoming less popular than what may be called the operations of chance. Asepsis permitted a rashness which displaced the consideration of the right of a given human entity to the benefit of a doubt, and made the exploration of almost every heretofore uninvaded area in the body, and the removal or rearrangement of its contents a successful possibility; modern surgery thus by its brilliancy invited a boldness which led away from the sound principles of conservatism. But however far the comet may turn from the sun in its long orbit, there must be a return; and the thoughtful surgeons of today have called the attention of the medical profession to the abuses that enthusiasm, often unfortunately accompanied with insufficient training or natural talent, has begotten. The reasonable and logical result has been the organization of a college of surgery, through which ultimately may be brought about the standardization of the surgeon and the dream of a rational surgery; for it is to be assumed that surgery is passing through a stage not wholly dissimilar to the stage of over-medication in medicine.

Although the abuses incident to the treatment of medical diseases were but slowly recognized, absolute empiricism finally giving way to a rationalism secured only through the tedious building up of a scientific medical structure,—and although the elaboration of surgical technique made possible surgical procedures not wholly consistent with the natural limitations of every useful applied science,—there is a similarity in the excesses in these two branches, medicine and

surgery, that over-enthusiasm may create, which should lead to a further questioning of methods that charm and captivate, and at the same time may confuse.

The success of medical or surgical treatment requires an accuracy which must be based upon thoroughness of diagnosis. This is the first essential, and it may also be considered the leading perplexity. To the fundamentals, anatomy and physiology, have been added pathological anatomy and pathological physiology, naturally stimulating an elaboration of diagnostic methods, intricate as well as comprehensive. We would certainly wish to absorb and possess these essential aids to success, but there are human limitations; we are willing to admit mental lapses when we do not think—not to be classified as true examples of ignorance; we are conscious that our judgment is subject to the usual frailty of deductive reasoning based upon premises which have not arranged themselves with sufficient clearness of mental vision; we are not immune from the possibility of becoming narrowed to a line of thought, that tends to the grouping of problems of obviously different nature into the class of causes to which we have given serious and earnest attention; we would even plead a disinterestedness and a disinclination to assume a given responsibility, as impairing a clear conclusion. These cause errors, which, while not insuperable, may be condoned as chargeable to inherent weakness, unrealized or confessed. But our real perplexities must first arise with the conscientious attempt to form an opinion that shall be free at least from the charge of incomplete examination. At once the clinician is confronted with the necessity of deciding whether in the light of modern methods he is reaching a superficial conclusion or whether he may not be indulging in an over-elaboration entirely unwarranted.

It is to be assumed that certain fundamental principles in our search for the diagnosis are always necessary, involving the intelligent answering of such questions as may be pertinent to the case.

There can be no controversy upon this point; and the more detailed and accurate, the more valuable the wisdom of the opinion sought. But there may arise today certain doubts as to the completeness of an examination, if history, and the routine of inspection, auscultation, percussion, palpation, and urinalysis, alone are deemed sufficient: these were the methods which a quarter of a century ago were considered, if completely and carefully executed, as the acme of a technical alertness quite all-sufficient.

In our large hospitals the little laboratory in some inconspicuous room had not been replaced by the modern hall of research, with its corps of assistants, that occupies such a conspicuous place in modern hospital equipment, and makes available the many present day accessories to medical and surgical practice. Small wonder

that the contemplation of the rapid stride of medical progress in this single phase of better diagnostic helps and the multiplication of the methods now necessary to a thorough and complete examination, leaves the mind of the practitioner of twenty-five years in a maze of doubt and perplexity, and with a peculiar sense of unfitness for his daily problems.

It is easy to conceive that the stupendous requirements in this field of diagnosis alone are accountable in no small degree for the growth of specialism which it is stated now has an enrollment of thirty-four claiming distinction. The "isms" of the old days, representing the evolution in medical progress of many quarter century periods were not so numerous. This rapid division of labor and its apportionment in our midst among the discerning, who from special interest, from opportunity chosen or compelled, or from a desire to be relieved of the tedium of general practice, saw the hand writing on the wall, was clearly a necessity.

The same query of human limitations urged a solution of complete or incomplete mastery of the complexities of medical knowledge, and to which perplexity there could be but one answer, a division of the work. Although specialism was fully justified for this reason,—its modest beginnings being contented with a refined ability in diseases of some of the special senses,—there could not be foreseen the numerous subdivisions its scope would include; and while there is much that is good in the allotment to specialists of the difficulties that are obviously best treated by the hand, the eye, the ear,—with its brain skilled in the interpretation of their discoveries,—certain abuses must be admitted to have arisen, detrimental alike to practitioner and patient.

The rise and growth of specialism have been the result, not alone of its necessary existence, but also, as has been hinted, owing to the rapid advancement of medicine in diagnostic methods applicable through laboratory research, and through instruments of mechanical precision. The memory is easily recalled of charts whereon was summarized in orderly arrangement all that was needed to classify the particular renal defect that the unfortunate producer of the specimen at hand possessed; it was held possible thus to differentiate any one of a dozen important and different conditions irrespective of any other knowledge of the clinical problem. As often happens, the increasing minutiae of examinations, designed to have a purely helpful and practical application, actually deprive them of their first intrinsic value, and result in a detailed procedure, possible only to the specially skilled; the promise of new vantage is thus shorn of its usefulness in the complexity brought about by its illogical and exaggerated growth. Moreover, the simplification of diseased conditions that seemed to warrant several subdivisions, may so change the anatomic or the clinical grouping, that a large portion of the analysis is rejected as

unnecessary, since the lesion sought can often be determined by a few essential tests. When also, in addition, a widening intelligence discloses that the urgent problem in the clinical consideration of disease is the functional capacity of organs, the old perplexities, attendant upon the elaborate estimation of the finer pathological changes, are replaced by newer ones for determining functional efficiency.

The task is always the problem of applying necessary tests in as concentrated working form as possible.

The same criticism may be applied to hematology: that it has solved some problems, and gives the diagnosis in a few diseases is to be admitted; that routine examinations of the blood are comforting in their negative findings; and that hematology may give hints to conditions quite distinct from diseases of the blood itself, is well known; but a few simple tests have supplanted elaborate ones except in cases where a systematic search is required, and the great expectations of the earlier days in its rise as a laboratory method of the greatest importance have been disappointing, and added another to the list of diagnostic uncertainties.

Similar experiences have befallen our hopes in other methods, which seemed about to solve many of our vexatious problems. The introduction of the stomach tube for diagnostic purposes led to the firm belief that at last the field of gastric complaint would be cleared of its uncertainties; that it has given us much that is to be considered as a valuable addition to our medical knowledge none can deny; but that its use has resulted in any marked simplification of diagnostic difficulties can neither be affirmed. It is possible that too great a demand in the beginning was put upon this functional test in the expectation that it would reveal decisive characteristics. The process of unlearning has always been in evidence in all scientific advancement; the constant tearing down of the structure can alone give ultimate stability. Always there exists the intricate and manifold mutual relationship between diseases, causing often a confusing symptomatology, and a failure to find in elaborate laboratory methods the solution sought.

There is a certain refreshing charm in Fitz's clearness of vision when he says in his monograph—"The Diagnosis of Abdominal Disease": "An attempt to make a differential diagnosis of abdominal disease demands in the first instance an available knowledge of topographical anatomy—the knowledge which needs constantly to be refreshed and controlled by frequent attendance at post-mortem examinations, and repeated observation of surgical laparotomies."

It is not to be inferred that any rebellious thought is intended in mentioning certain fallacies commonly encountered in laboratory methods; these methods must constitute a part of the armamentarium by which the older ways of reaching a diagnosis are to be more and more

supplemented. Nothing but praise and admiration is due the patient investigators, who with the real spirit of discovery have toiled at what is often a disheartening task, laboriously searching every pathological condition causing a variation in the body's waste, in its chemistry, its fluids and secretions. They have led the way to vaccine experimentation through the theories of immunity, and they have made easy the knowledge of the presence of certain latent diseases that before could have been only vaguely and imperfectly suspected by the keenest analysis. But their stride is a difficult one to follow and may lead us in our enthusiasm,—to quote Reynolds in the *British Medical Journal*: "To forget that the old methods of examining a patient, conducted by the more or less unaided senses, including that very necessary sense, common sense, are just as much scientific methods as examination by the most elaborate chemical or physical method."

The whole of a man is not the sum of his parts, and the whole of the medical profession is not the sum of its specialties; neither is the knowledge of the sick body to be acquired by the totaling of its laboratory returns. The old standards and old distinctions, however inadequate they may have come to be, must not be dismissed in the desire to do the last new thing.

Workers in the field of Roentgen diagnosis are among the latest experts to appeal to the profession; the earlier assistance that Roentgenoscopy gave in the detection of foreign bodies, the pathological lesions of the body's bony framework and the shadow pictures of the chest, has taken on a new interest with its more elaborate work in connection with the internal administration of bismuth; first, by its demonstration of the presence of certain functional disturbances, notably those of motility and exaggerated sensitiveness; and later with the assumption of its ability to detect anatomic lesions themselves. But difficulties attend positive conclusions; the weight of the bismuth and the mental state induced by the examination are not negligible sources of error; and owing to the fact that lesions of the pelvic organs, alkaloid and other toxemias, and diseases of the nervous system, apart from those associated with the digestive tube or its adnexa may occasion an irregular behavior of the bismuth stream,—the positive diagnosis must often be attended with doubt, and at times a negative finding proves misleading. Those who zealously advocate the use of the x-ray examinations as an aid to diagnosis are frank to confess that in almost the whole of certain cases,—as, for example, duodenal ulcer,—the radiologist's work has been confirmatory, and a definite diagnosis reached by the older methods; and to the same pass has come the once infallible proof of syphilis, the Wassermann reaction. In gastric cancer similar uncertainty confronts us in the results obtained in the search for the early and important suspected cases.

While the confusion that exists in the minds of many as to the unquestionable value of Roentgen diagnosis may lead to a reasonable doubt, a wise skepticism should, in admitting its limitations, recognize its value as an adjunct to other methods in difficult cases, but not as an independent procedure.

The enthusiasm that each new diagnostic method arouses tempts the practitioner to lean too exclusively upon it, to the detriment of his hard-earned powers of deductive reasoning; credulity is his besetting weakness, and he too often accepts, without sufficient evidence or inquiry. But there is danger, too, that the thought of the absolute certainty of laboratory and mechanical methods may lead him to side-step, as it were, the responsibility that a diagnostic perplexity presents; the feeling of doubt may be easily fostered and he may decide to help himself out of his difficulties by the easier path of referring his patient to this or that expert; the eventual waning of his ability as an independent thinker must result. In these days, when the pace of scientific precision staggers the busy doctor with the helpless feeling of incompetency, the thought of one of the requirements of fitness should stand high in all perplexing moments, namely, self-confidence. The words of Emerson in his essay upon "Self Reliance" may very properly and fittingly be recalled: "A man should learn to detect and watch that gleam of light which flashes across his mind from within, more than the lustre of the firmament of bards and sages. Yet he dismisses without notice his thought because it is his... The power which resides in him is new in nature, and none but he knows what that is that he can do, nor does he know until he has tried." "A spur on the head is worth two on the heels." Whole-hearted, independent work contributes something to progress; and the doubts that must arise in a contemplation of the rapidly increasing number of new diagnostic details should not terrorize or stampede the practitioner to a belittling of his ability to select what may seem to him pertinent to the occasion. This ultra scientific century compels us to consider seriously whether all that is sneeringly called empirical must go down before this wave of scientific medical evolution; should this momentum of growth continue, its adaptation to the subject of medical training must result in a questionable efficiency, so vast and complex will its requirements have become; for a given scientific attainment of high degree in any one field of knowledge necessitates an obliteration of all other broader and comprehensive thinking: the specialist confines himself to one realm, and views with disdain or suspicion the older education as obsolete and of little practical utility; yet it would seem that an education based on a too narrow application of purely scientific methods must lead to a neglect of the underlying elements of medical success—anatomy, physiology, pathology—which must be admit-

tedly the tools for intellectual work. In addition, for the practitioner to attempt to acquire and apply accurately the great mass of detailed work resulting from laboratory and mechanical experimentations is futile, because, as has been seen, much of it becomes quickly obsolete as a working asset. Too great an emphasis cannot be put on what has been learned by experience. The practitioner should not permit the lack of acquaintance with newer diagnostic procedures to intensify the many perplexities of his vocation, but should employ a calm attitude of reasoning when to solve and when to refer. We need all the old originality and independence, controlled by an analytical sense of discreet inquiry through others and by laboratory helps.

The world has always demanded the full equivalent for value received, but never more so than today; and while we must be guided by the standard of the times, and the people with whom we are dealing,—the amplification of present-day methods, in reaching a conclusion through expensive eliminating routes, which lead the patient to an outlay of money quite unanticipated, should be carefully considered. Although the public has the right to demand what may be called modern refined methods of diagnosis, and to expect treatment based on scientific accuracy, it is not possible to apply at the home or in the office such painstaking scrutiny to all cases of doubtful diagnosis on account of the expense suggested. It is evident that surgery owes no small part of its success to the fact that within a double decade it has transferred its work entirely from the home to the hospital; where, with the facilities afforded by the latest modern equipment, seconded by the assistance of a house staff well qualified to utilize any of the more intricate and time-consuming aids to diagnosis, it has been able to reach conclusions more nearly correct and to secure proportionate results. And it is probable that the experienced, thoughtful man of medicine should more often follow the example of the surgeon, and secure for his patient at a reasonable hospital expense the refinements for diagnosis that selected cases may seem to require. In this way he will render a service more in keeping with the spirit of the times, and secure for himself an assistance which will enable him to bring a perplexing problem more often to a brilliant solution.

It may be undeniably true that incomplete examination and careless thought, due largely to lack of time, are the cause for the largest class of mistakes that arise in diagnosis; but Cabot's figures have shown that even when a conclusion is reached by the most careful clinical analysis, checked and aided by laboratory findings, which few practitioners can command, nearly one-half are erroneous; similar statistics in the future will undoubtedly show a marked improvement in the imperfections now present, but to many of us these acknowledged limitations may

prove a source of comfort, as well as an impetus to more determined endeavor.

The diagnostic perplexities in modern medicine that must more urgently and constantly assail us than ever before should enlist powerfully our sympathies with the great mass of medical men who occupy the first line of trenches, and receive first the impact of the attack; while the specialist and the expert are necessary to the particular detailed work of the campaign, it is the general practitioner that must bear as yet the brunt of the fight and make up the "line of steel," even as in modern military warfare.

Finney in his address upon the "Standardization of the Surgeon," says of the surgeon, "An error of judgment in diagnosis, or in execution, lack of familiarity with the latest approved methods of dealing with certain conditions, defects in technic, and many other considerations, some of them apparently minor, may decide, and frequently do, between a happy restoration to function or to health, and a life of invalidism; between life and death." The responsibilities that assail the practitioner are not one whit less, although he may not be as directly accountable for the operation where judgment and dexterity are all essential; and while the thought of his standardization may not take on the form of organization for the purpose of reforming his defects, more thought should be given him in offering opportunities whereby he may continue his education in the light of newer advances, and so amplify and direct the continued cultivation of his powers of observation. And there are signs that the physician of the future will demand an opportunity to partake with a livelier interest in the advantages that today accrue to the few who are in close touch with large medical centres.

The serious problem, for those who would in any way standardize the working efficiency of the great numbers of our profession and advance the high character of medicine, must be the problem of continued education after graduation. Books and periodicals are too voluminous for the busy man to digest; and the mind in the variety of its confusing thoughts is robbed of the symmetry of studious analysis; clinics are small and unfortunately benefit only the few that are favored with hospital appointments; our medical societies, associations and clubs provide a certain valuable interchange of thought, or receive didactic instruction from eminent medical gentleman who gladly give of their time and personal endeavor.

We must never lose sight of the fact that knowledge gained through the ear is more truly gained and more surely retained than what we learn from the eye.

But as yet our universities have not provided any plan whereby post-graduate instruction can be extended to any except those fortunately nearby; the Fellow living at a distance is neg-

lected; he cannot avail himself of the present instruction to graduates except under a stress of difficulties which are well known. In some way his opportunities for growth and service should be increased. Recently the Massachusetts Medical Society has joined in the publication of a journal which is to be its literary gift to its Fellows; and it is to be hoped that a near future may see this splendid society, ever serious and foremost in its efforts for medical advancement, formulate some plan whereby didactic exercises, offered in different localities, may stimulate its members to better work and provide a late knowledge of whatever may be scientifically conservative in medical practice. The way would seem to be already opening to the accomplishment of such an idealistic beneficence; for only recently it has become possible for our Fellows, for a most modest fee, to receive for individual analysis or group discussion the records of such clinical cases at the Massachusetts General Hospital as have a completed value from the pathological findings.

Today the thought of university work cannot confine itself to resident student life; the university should not be the place where the student has once studied and received once for all his education; too often the impulse given will retrogress, and suffer loss in its potential value unless continuously cultivated; the kind of study for which it has prepared him may well be enhanced by its fostering care; and in no department more to the public good than in that of medicine.

"Mental laziness" is an easily acquired habit for the tired busy practitioner, and some stimulus is needed to arouse him from his intellectual hebetude; success in practice mitigates too often the pride in exact thought and his ambition may even reach the stage of "getting by" with his professional duties, and declining to become interested in the definite problems that may present themselves. Modern medicine makes it more difficult for the young physician to succeed for several reasons, not among the least of which is the cultivation of laboratory refinements at the expense of the older methods requiring more careful logical reasoning; and having succeeded may make it easier for him to neglect his vantage ground, because of the rapidity of change which always characterizes any ultra-technical enthusiasm. "The race is not always to the swift." Until that time when the whole field of medicine shall be perfectly covered by science, it may be well in daily practice to retain a rational empiricism and at the same time prudently to refrain from attempting to be too scientific. Ovid wrote: "Medio tutissimus ibis."* The public looks for quick results; the busy man of affairs, whose motto is "deliver the goods"; the devotees of society or the latest fad of "advanced thought," have no time to spare in illness; laws or acts of compensation, which apply to certain employments,

* *Metamorphoses*, II, 137.

make no appeal to them; and they demand that our services shall promptly overcome nature's defects and deficiencies, tolerating impatiently a conservative growth. It is a stimulus that men of science feel—it is a whip that tends to develop laboratory research apart from careful clinical coöperation; it results in a tendency to complete therapeutic skepticism and nihilism, and to the lessening of the appeal to the art of healing in favor of the science of the investigation of diseased processes.

We are not assuming that the problems and perplexities in modern medicine are essentially greater than our forefathers experienced; whenever a human problem has arisen, the past has given men who seriously faced the difficulty and secured results which seemed to serve the purpose as well at one time as at another; so that in our thought of progress, tending occasionally to become a trifle vainglorious, we need not indulge too extensively in pity for the ignorance of the old practitioner, who was a doctor, yet could not according to our conception glorify his title with the easily commercialized term "scientific." However, relatively our problems seem more difficult; numerically they obviously increase; but this increase is compensated by a division of the labor. The last century saw the medical thought more constantly directed to the care and cure of the diseased individual; now there is added the care of the public as a whole—preventive medicine in its many aspects, embracing that very important problem, the reduction of the number of those seriously ill at any one time; estimated by Prof. Irving Fisher of Yale as about 3,000,000 people in the United States, one-half of whom are suffering from preventable causes; for although mortality as a whole, and more especially in certain diseases, shows a decrease, there are those who maintain that morbidity has actually increased.

This view is certainly illustrated in the increase of acute diseases of the respiratory tract; whole communities are made miserable, and the feeble and non-resistant seriously menaced, by these endemic or epidemic outbursts of bacterial infection, spread by the tiny droplets of germ-laden moisture, sneeze or coughed from carriers in the presence of others. The number of enteric infections and the more serious of the contagious ones, scarlet fever and diphtheria, that the physician is called upon to attend is lessening, owing to the persistent fight of our public health boards in securing legislative insistence upon the elimination of dangerous sources of dissemination,—notably impure milk. But the problem of the control of these riotous infections of the air passages has secured as yet scant consideration; and the common "cold" continues its supposedly benign existence without "let or hindrance" by the public and with too little appreciation of its possible gravity by the profession.

With the thought of prevention and control,

more especially adapted to the preservation of life in its earlier decades, when susceptibility to bacterial invasion is most marked, has come the consideration of prolongation of life at a time when its economic value is enormous; already recognized by life insurance companies as an asset in their business methods of no little importance, there is a growing tendency among men of affairs to seek for possible defects in the physical economy, which if known and mitigated or remedied, may enable them to lengthen their lives; for it seems to be a fact that our vital organs wear out sooner than did those of our ancestors.

While this phase of practice may have been an incident occasionally in the work of physicians, its application along the broader lines of an exact knowledge of what constitutes normal physical conditions and a healthy state of organs, necessitates a critical survey and balancing of normal and negative findings, no less perplexing than the hunt for the suspected pathological state; and it implies a renewed cultivation of the judicial qualities in medical men that makes their advice and not their prescription so valuable in a community. We are coming to consider and care a great deal for the problems that pertain to the public as a class in standards of living and material well being; and always with the thought that future generations will receive a richer heritage of health than fell to ourselves, to say nothing of the preservation of the human race. Personal advantage and the isolation of the individual welfare must be dominant thoughts and ambitions, but a widening knowledge and experience bring a clearer understanding of responsibilities. The rack of hurrying medical progress need not torture us with its perplexities, if, while entertaining a wise regard for the newer teachings of science and a deep appreciation of men of attainment in their special field of knowledge, we cling more closely to the thought and wisdom born of experience.

We are constantly reminded that this is a wonderful age: its qualifying adjectives are many, and not the least impressive is the one, scientific; implying that all things claiming excellence and merit, must receive the stamp of the investigator in approval before they can be unhesitatingly used; everything is to be viewed in the light of the cold, impassive man of science; but there is danger of making standards too high for practical purposes—above the perceiving level of the public—beyond the absorbing power of the man who is expected to weigh and make application of this scientific evidence.

Perhaps when this generation has gone, the coming generation will demand less of that close trusted relationship between patient and physician which has given a unique charm to our professional life; the efficiency test may prevail to the obliteration of the necessary management of the whims and vagaries of the patient; his in-

telligence and passivity may permit the detailed routine of an exactly applied scientific performance, such as we now cannot, if we would, secure. Until that time comes, the word of sense and sympathy must not be supplanted by the last one upon which science has placed the stamp of approval; and during this rapid evolution of medical progress our duty is simple,—to attempt to think logically and sanely with such humble powers of observation as we may possess.

In the consideration of some of the doubts and perplexities that every conservative physician must entertain, there should be no morbid pessimism about the future; we do a double duty in each problem solved in making as individuals for the continued progress of medicine; yet there should not be a too great readiness to detect disease, lest we become incapable of receiving all the evidence, having our thought concentrated upon some new infallible method of our own or another which may seem to surmount old-time difficulties and give a sense of security and knowledge. While diagnosis is the most essential demand in our work, it should not make us careless of the growing cry for the cure of every condition or disease to which our bodies may be subjected; the important consideration of treatment may be neglected; we take the patient readily and gladly into partnership and discuss volubly the scientific aspect of his case, contentedly feeling that we have vindicated our conclusions beyond any questioning thought. This attitude of what is most essential is from our own view-point; the problem and the accuracy of its solution, while vital in the quest of perfect knowledge when possible and the necessary forerunner of intelligent treatment,—coöperation of the patient and the maintenance on his part of a lively sense of the result to be obtained, while comforting and stimulating to the physician, do not constitute the whole perplexity that confronts the patient; the refinements in methods are of less interest to the subject than their results. His appeal, and his trust in that appeal, should leave but one fixed purpose,—his mental or physical relief; and the downright heartiness of that endeavor requires a sagacity acquired in no one of the physician's many workshops of learning.

We are gradually acquiring through the natural development of the processes of medical growth a system for the scientific management of disease. The past is full of stimulating traditions; the present, filled with the grains of precious wisdom that have been extracted from the mountains of theory and conjecture; and we accept the truth that in the future what we now worship will be swept away in the melting-pot of scientific ardor. But in admitting our limitations, we affirm with greater confidence our optimisms. It is only when harassed and perplexed that men learn; "strength grows out of weakness." The ideal of medicine demands for its consummation, individual exertion and un-

tiring enthusiasm. Each contribution, whether of the laboratory,—from the special research man,—or of the great hospital and private clinics, from the more practical observers and teachers—successful practitioners of well-deserved repute,—or of the storehouse of experience, from the great class of silent, thinking medical men,—each factor is an atom, akin to the body of the tiny coral insect, in the building of the enduring structure of the "Goddess of Medicine."

The poet sings,—

"Grandeur of the perfect sphere
Thanks the atoms that cohere."

And of the cohering elements entering into the structure of medicine by no means the least valuable is the country practitioner, who, alone and remote from all enthusiasm and support, often surrounded by unsympathetic critics, goes ahead and does his work as he sees it.

It is easy to be a soldier when you have a soldier on every side of you; over-courage is born of the crowd; but the yeoman service is his who, enduring—

"Chance and victorious death,
Life and his doom obscure,"

learns the secrets of sickness from his lonely struggle with it.

To support, not suppress, this type of man should be our objective; to assist his patient observations of his patients' symptoms and story with rational laboratory research should be our ideal.

THE RELATION OF BACTERIA TO THE ETIOLOGY OF SUMMER DIARRHEA IN YOUNG CHILDREN.*

BY ARTHUR I. KENDALL, M.D., CHICAGO.

[From the Department of Bacteriology, Northwestern University Medical School, and the Sarah Morris Memorial Hospital, Chicago.]

THE subject for discussion this evening is one that has stimulated much controversy, and the final solution of the problem is apparently remote. The object of this presentation is to point out certain features of the problem which have caused confusion in the past and to mention briefly certain unusual observations which may have led to erroneous conceptions of the part played by bacteria in the causation of acute diarrheas. To avoid ambiguity at the start, only those severe summer diarrheas will be considered in which the pronounced clinical symptoms are

* Presented before a meeting of Pediatricians of the Middle West, Oct. 29, 1914.

observed to be fever, prostration, vomiting, and, frequently, nervous symptoms, together with mucus in the movements, often associated with pus, or blood, or both. The movements *per diem* are increased in number and reduced individually in amount.

Many theories have been advanced to explain the etiology of these summer diarrheas, some of them very elaborate and comprehensive,—but for purposes of debate the underlying principles of these theories may be reduced to three rather distinct groups. It is to be definitely understood that these three respective theories attempt to explain only the initial cause of the diarrhea in each instance; secondary complications which may arise during the course of the disease are eliminated for the moment.

1. The Meteorological Theory. This theory assumes that high temperatures experienced during the summer months, usually in association with high relative humidity, initiate nervous and metabolic disturbances of greater or lesser severity, particularly in young children, which lead to the train of symptoms just mentioned.

2. The Physiological Theory. According to this theory, dietary indiscretion, or perhaps the temporary inability of the young child to assimilate food, is the primary inciting factor of diarrheal disturbance. This dietary indiscretion, which may be further complicated by secondary, endogenous bacterial involvements, leads to nervous and metabolic disorder, as well as an intolerance for certain types of food, carbohydrates and salts appear to be the more common food elements which lead to this syndrome, according to the most widely accepted of these physiological theories.

Both of these theories—the environmental and the physiological, tacitly assume that the patient is not a source of danger to other children, for there is nothing inherent in either of these theories which would point to infection with exogenous bacteria. Endogenous bacteria do not, as a rule, cause progressive disease from man to man.

3. The Bacterial Theory. This theory, as the name implies, asserts that specific bacteria, or combinations of bacteria, are the primary etiological agents of certain of these diarrheas. The bacterial theory presupposes that a specific organism, or association of organisms, is actually identified before the diagnosis is arrived at. The

patient, according to this theory, is a potential menace to other children.

There is no doubt that each of these theories best explains a certain proportion of these diarrheas, and it is equally probable that combinations of heat, food and bacteria are responsible for many others; furthermore, from season to season, one or another theory may be found to be the more important factor in a majority of the cases under observation. Doubtless, also, as more exact information becomes available, it will be found that sectional differences of opinion which prevail at the present time will be reconciled, and that these differences may be attributed reasonably, in part at least, to actual differences in the material under observation in different places. Indeed, there is strong presumptive evidence that the summer diarrheas seen most frequently in Germany differ in type and severity from those which have prevailed in the past in the large cities along the Atlantic coast of the United States. A very simple explanation presents itself. Cow's milk is a very cosmopolitan children's food both in this country and in Germany; in Germany milk is customarily boiled before it is fed to infants and young children, whereas in the United States, in the East at least, it is not boiled as a rule; in fact, it is only comparatively recently that pasteurization has been generally introduced in this country. Milk is a particularly good vehicle for the transmission of bacteria, and it is a significant fact that the majority of disease-producing organisms which may be thus transmitted through it from man to man are those whose portal of entry is the gastro-intestinal tract. When one recalls that the type of disease under discussion is probably gastro-intestinal in origin, it is not surprising to read that bacillary dysentery and similar diseases of bacterial causation are comparatively rare in Germany; the organisms causing this type of disease are non-spore-forming, and, therefore, readily killed by the boiling temperature to which milk is subjected there. On the contrary, bacillary dysentery and similar infections are, or were, relatively common in the eastern part of the United States, where in the past the "dip tank" no doubt contributed a formidable amount of infection to and through the poorer classes, whose poverty necessitated the purchase of small amounts of milk at one time. It should be remarked parenthetically that the more general pasteurization of milk and the activities of the Infant Welfare

Stations have been accompanied in this country by a marked reduction in the incidence and severity of this class of disease, which no longer appears endemically summer after summer as formerly, but rather tends to appear sporadically. The bacterial diseases transmissible through milk in Germany would theoretically be caused by spore-forming bacteria, and it is a significant fact that the most common treatment of severe feeding cases in that country, administering Eiweiss Milch, is essentially the one which experience has shown to be efficacious in the United States for the treatment of at least one perfectly definite infection by a spore-forming bacillus which is transmitted in milk—the “gas bacillus” (*B. aerogenes capsulatus*). Indeed, cases are on record where infection with this organism has developed in hospital wards following the administration of lactose, which was found subsequently to contain a large number of spores of the “gas bacillus.” This is not to be construed as a suggestion that all the feeding cases and diarrheal cases seen in Germany are due to the gas bacillus,—probably the reverse is true in the majority of cases.

Returning once more to the discussion of the theories of summer diarrhea, there are occasional cases of sudden severe illness, frequently with a temperature of 102-103°, marked prostration, vomiting, and diarrhea, which respond promptly and favorably to suitable changes in environment, together with the withdrawal of all food for 24 hours, if these patients are seen in time. These cases are encountered not infrequently in excessively hot, humid summer weather; their prompt response to proper changes of environment suggests strongly that the chief etiological factor is environmental, namely, heat and humidity. Ordinarily these cases are not numerous.

Dietary indiscretions are undoubtedly far more common causes of summer diarrhea. Uncomplicated cases, provided they are seen early, usually show decided improvement within 24 or 48 hours following the withdrawal of all food; the temperature abates, and the acute symptoms subside, although they may, and not infrequently do, develop into more or less chronic “feeders” with persistent abnormal movements.

The severe bacterial infections differ from the preceding types in one important particular, so far as fever is concerned. Even if the patient is

seen in the early days of the disease, the fever persists for several days, in spite of the withdrawal of food, and the substitution of a proper environment. The patient usually becomes progressively worse, for a time at least.

The most annoying physical features of severe diarrheas of bacterial causation is the similarity of clinical symptoms elicited when widely different types of bacteria are the etiological agents; the general clinical response to infection on the part of the patient gives little definite evidence of the nature of the invading organism. The symptoms overlap, as it were, and for this reason it is necessary to resort to other than purely physical signs to establish the correct bacterial diagnosis. This is particularly true of severe infections; mild infections may so closely simulate the symptoms of dietary indiscretion, of thermic fever, that a definite diagnosis is frequently not made.

This leads to a very important question: How differentiate the three types of diarrhea, and what value has a bacterial diagnosis in this connection? A bacterial diagnosis presupposes the services of a well-equipped laboratory, which is not always available. In the past, furthermore, a bacteriological diagnosis, even if it were made properly, has done no more than to catalog certain bacteria which are presumably the cause, directly or indirectly, of the disturbance. The chief value of such work has been to furnish names for certain types of disease, thus adding definiteness to the diagnosis, and to warn the clinician that the patient is a potential source of danger to other individuals. Thus the net result of such an examination is diagnostic and preventive; the all-important factor to the patient—the suggestion of a definite line of treatment—which is at least theoretically desirable—is not touched upon. Undoubtedly this paucity of information has led many clinicians to frown upon the laboratory, they believing with a great deal of reason that the laboratory examination is not worth the trouble expended in obtaining it, and the tendency has been for empiricism to replace laboratory investigation. It is a noteworthy fact, however, that empiricism, based upon keen and extensive observation, very frequently leads to the same general action as would the more direct laboratory investigation; indeed, the practice of medicine has been largely developed by this empirical method.

There are certain peculiarities in the seasonal distribution of types of bacteria which cause summer diarrheas, which have tended to restrict empiricism, at least as it may be applied in the treatment of the more severe cases. Instances of this are well known; at one time or another every combination of milk proteins, milk sugar, whey, and cream have been used with varying success in the treatment of severe diarrheas one season, only to fail in whole or in part the next season. A specific example may make this assertion more definite. A large series of sick babies were treated indiscriminately with a preparation which was potentially buttermilk during an entire summer. The cases were not selected other than that they were all of the diarrheal type—mild or severe. At the end of the season these cases were collected and summarized, and the information gleaned from this treatment was placed on record for the benefit of those interested in the subject. The report was accurate in every respect and striking enough to induce others to try the same procedure the following summer. The results obtained the second season were disappointing, almost without exception. How is one to interpret this apparently paradoxical situation? A very direct and satisfactory explanation presents itself when the bacteriological aspect of these cases is unfolded. It has been stated that different types of bacteria may elicit the same general clinical response in young children—hence the similarity of symptoms observed during the two years is plausibly accounted for. The predominating organism isolated from the patients the first summer was the "gas bacillus," an organism which is more active in the intestinal tract when carbohydrates are present; the activity of the gas bacillus is considerably restricted, however, when protein replaces the carbohydrate of the diet. The addition of lactic acid to the diet appears to reinforce the favorable results obtained by feeding protein and restricting sugars. Buttermilk, properly prepared, combines the advantages of a protein diet and lactic acid. The patients seen the next summer differed bacteriologically from those of the first summer in that the dysentery bacillus was the dominant organism encountered, not only in the severe diarrheas, but in some mild cases as well. The "gas bacillus" had largely disappeared; only a comparatively few sporadic cases were found. The dysentery bacillus is habitually a proteolytic organism; it produces its poison, according to various investigators, chiefly, or only, in the absence of utilizable sugars. The presence of utilizable sugar in the intestinal tract tends to change the metabolism of the dysentery bacillus in such a manner that these poisons are either not produced, or produced in lesser amounts. Buttermilk has little or no influence in restricting the activity of this organism; indeed, buttermilk appears rather to aggravate the conditions in the intestinal tract, particularly in the more severe cases.

This explanation of the success and failure of buttermilk, as the type of dominant infecting organism shifted in two successive years, is probably not unique; it is possible that other, similar observations may be made in the future. It might be objected that the gas and dysentery bacilli, respectively, were not necessarily distributed seasonally throughout the country as they were in the East, thus weakening the argument somewhat. This objection cannot be definitely answered pro or con with our present knowledge, but for the relatively limited area in which this observation was made the explanation appears to be a valid one. In any event, it is obvious that the etiology of these diarrheas for the two successive years described could hardly be attributed to dietary indiscretion alone. If such were assumed to be the case, one would be forced to assume that there may be among young children a seasonal food idiosyncrasy which in the instance cited resulted in a rather general carbohydrate intolerance one year and a corresponding protein intolerance the next year.

A seasonal distribution of bacterial types appears to have been unrecognized hitherto, at least in association with diarrheas in infants, and a brief discussion of studies along this line made during four consecutive summers on the Boston Floating Hospital will illustrate more clearly how the dominant type of organism found there in cases of summer diarrheas varied from year to year.*

During the summer of 1910 by far the greatest number of severe diarrheas which entered the wards were those from which dysentery bacilli, either of the Shiga or Flexner type, or both, were isolated.

TABLE I.

Year.	Total Cases Examined.	B. Dysenteriae Shiga and Flexner.	B. Aerogenes Capsulatus.	Streptococcus.	B. Morgan.	B. Paratyphosus Alpha and Beta.	"Slimy" Bacillus.	B. Proteus.	B. Alcaligenes.
1910	52	39	22 ¹	7 ²	4	beta 2	0	0	1
1911	146	18 ³	33 ⁴	78	16	alpha 1 beta 10	2	8	5
1912	135	5	53 ⁵	6	13	beta 4	31	2	3
1913	457	35 ⁶	53 ⁷	5	29	beta 8	59	2	4

¹ 293 cases examined: 6 normal, 2 watery stools, 14 blood, pus and mucus.

² Organisms also found in variable numbers in 60% dysentery cases.

³ 3 undoubted carriers—no gastro-intestinal disturbance.

⁴ 283 cases examined;

⁵ All showed blood, pus and mucus in stools: majority of cases severe.

⁶ 18 carriers—mild diarrhea.

⁷ 11 severe cases; remainder symptoms mild.

* This great charitable institution draws its patients from the poorest and most crowded parts of the city; hundreds of cases are treated each summer, and a majority of the cases are severely or even desperately ill. Many patients have died as they were carried across the gang-plank, or shortly after they entered the wards; the little patients are only too frequently brought to the hospital so late that nothing can be done for them. The mortality from bacillary dysentery during "bacillary dysentery years" has been from 35 to 50% of all cases diagnosed.

In 1911, although the cases were apparently equally sick and the general clinical picture was about the same, dysentery bacilli were comparatively rarely found in the movements; streptococci, on the contrary, were very abundant. Pure streptococcus infections had not been met with in 1910. The sequelae of the severe diarrheas in 1911, furthermore, were those which would suggest a streptococcus etiology: general septicemia, acute nephritis, involvements of the middle ear, two cases of perforation, and peritonitis.

In the summer of 1912 a new organism was dominant, although occasional sporadic cases had been met with during the two previous years. This organism was *B. aerogenes capsulatus*, or, as it is more popularly called, the "gas bacillus." Typical severe gas bacillus cases present a clinical picture which is strikingly like the syndrome of true bacillary dysentery, but with this very important distinction. Sugars are not only well borne in dysentery cases; they appear to be of some material assistance in tiding over the sick patient. If the same sugars were fed to patients suffering from "gas bacillus" diarrhea, which, it will be remembered, present the same general clinical syndrome, it will be found that far from being well tolerated, these sugars are distinctly harmful. Following the administration of sugar to such patients, the temperature is rapidly increased, only to fall slowly to its original level when the sugar is withdrawn. That is to say, as desperately sick dysentery patients are intolerant of protein, so desperately sick "gas bacillus" patients are intolerant of carbohydrates.

The following year (1913) another organism, belonging to the capsulated group of bacilli, made its appearance. This organism appeared to be far less active in producing severe diarrheas than were either the dysentery bacilli, the streptococci, or the gas bacilli, and the general run of diarrheas this particular season was noticeably less severe in character than those met with in previous years. These capsulated bacilli were found in a very large proportion of the diarrheas seen in 1913. These bacilli, furthermore, were found to be rather widely disseminated in nature during that summer, not only in the intestinal tracts of babies, but even in certified milk, where they formed at times from 60 to 75% of the total bacterial count of such milk; in the majority of instances this bacterial count was within the 10,000 limit standard imposed in Boston. It was noticed that diarrheas actually developed in the wards when this milk was fed; these capsulated bacilli were invariably found in the movements. The simple expedient of boiling the milk, however, not only prevented further development of these cases, it also appeared to help materially in treating the cases which entered the hospital. The assumption was that the capsulated bacteria did not readily acclimatize themselves to the intestinal environment.

The question is not infrequently asked, how does one know that dysentery bacilli, strepto-

cocci, gas bacilli, or capsulated bacilli are the probable causes of these diarrheas? The evidence in the case of the dysentery bacillus is fairly convincing. Tremendous epidemics of bacillary dysentery have occurred in Japan in the past, and a few laboratory accidents are on record in which laboratory workers have accidentally swallowed dysentery cultures and have subsequently developed typical cases of bacillary dysentery. There is a certain amount of evidence also which would indicate that children have developed bacillary dysentery in hospital wards apparently from other patients. More direct evidence is furnished by a few cases from whom the dysentery bacillus has been isolated directly from the blood stream before death. At least three authentic cases are on record. Finally, at post-mortem examination, the lesions of bacillary dysentery are characteristic and agree in essential details with those observed in the fatal cases in Japan, and the serological reactions are specific and characteristic.

The evidence pointing to the streptococcus as the etiological agent of one type of diarrhea is somewhat less direct. Finding the organisms in unusual numbers in the movements unassociated with other pathogenic bacteria, and the complications, particularly septicemia, nephritis, and middle ear infections, in which the streptococci are recovered from the blood stream or from internal lesions, furnish the principal evidence. It should be remarked parenthetically that these complications are usually not found in dysentery or gas bacillus diarrheas, although streptococci are undoubtedly present, frequently as secondary invaders, in true bacillary dysentery infections. The post-mortem lesions of streptococcus diarrheas are quite different from those of bacillary dysentery, although the symptomatology is much the same in the severe cases.

With respect to the gas bacillus, a few post mortems that have been obtained did not exhibit intestinal lesions which suggest either those of bacillary dysentery, or streptococcus infection. The striking macroscopic lesion appears to be for the most part a necrosis of the solitary lymph follicles of the intestinal tract, but these lesions are so limited that one wonders where the large amounts of blood, pus and mucus, which are a feature of the movements of these cases, originate. One of the most striking physical features of a gas bacillus infection is the curious and usually definite response on the part of the patient to the feeding of sugar. The response of gas bacillus cases to protein diets, including buttermilk and Eiweiss Milch, brings them into prominence in comparison with the experiences of Germany and parts of the United States. The gas bacillus is one which thrives on carbohydrates, and its activity is greatly increased by the presence of sugars. Consequently, it is not surprising to find that babies having well-defined gas bacillus diarrhea are harmed by feeding of sugars. The clinical manifestation of this result is a rather prompt and decided rise in tempera-

ture. The withdrawal of sugar and the substitution for it of protein, or, better, buttermilk, which contains considerable amounts of lactic acid, not only tends to bring the temperature back to a point approaching normal, but also to bring about a rather marked and comparatively rapid improvement in the symptoms. It is worthy of note in this connection, furthermore, that the gas bacillus which thrives on carbohydrates in the intestinal tract does not produce symptoms of toxemia in uncomplicated cases. Its effect on the patient in this respect is markedly different from that of the dysentery bacillus in which toxemia is a prominent factor. The effects of the severe toxemia, which is a feature of severe dysentery cases, persist after the cause of the toxemia is removed; many of these patients are unable to rally and eventually die from the effects of this toxemia in spite of treatment. The line of demarcation, clinically, between toxemia and extreme prostration is not sufficiently noteworthy to make this a very important diagnostic point, particularly in young children. It might be remarked parenthetically that evidence is accumulating which would indicate that the gas bacillus may be a more important organism in producing disease than has been generally suspected. It was first recognized as the cause of gaseous phlegmon, but evidence is available now which would indicate that at least in certain years it is a potent factor in the production of severe gastro-enteritis, not only in children, but in adults as well, and that in adults particularly it may lead to chronic intestinal disease, which may be accompanied after considerable periods of time with symptoms suggesting arthritis. The organism in a somewhat modified state of pathogenic activity has been actually isolated from at least one case of middle ear infection and from a case of chronic hypertrophic tonsillitis.

The gas bacillus is ordinarily regarded as an organism which is invasive, and the gaseous phlegmons referred to above are striking examples of such invasion following traumatism. Their activity in the intestinal tract rarely, if ever, leads to general systemic invasion. A certain amount of indirect evidence in favor of this view is afforded by the intravenous or subcutaneous introduction of dextrose into the body. If such a sugar is *fed* to the patient, it meets the gas bacilli in the intestinal tract with an almost immediate response on the part of the patient, shown by a rise in temperature. Sugar introduced *parenterally* into the body does not produce such a rise, even though large numbers of gas bacilli are active in the intestinal tract.

The discussion so far has related chiefly to the bacteriological diagnosis of certain types of summer diarrheas, and the evidence presented in connection therewith has related to the clinical and pathological features of these cases, which appear to confirm these opinions. An explanation of the seasonal alternation of dominant bacterial types is not so readily accounted for. Whole-

sale active immunization of the population from year to year could hardly explain the facts, for many of the patients under observation each summer were less than one year of age.

It is necessary to turn for a moment to the natural history of disease for a possible explanation of these alternations of bacteria. From time to time there have occurred world-wide pandemics of certain bacterial diseases. One of the most noteworthy of these is that great pandemic of influenza which swept over the world some three decades ago. This pandemic was a very widespread one with many fatalities. It will be remembered that it appeared first in Russia, it swept west to the Atlantic seaboard, appeared some two weeks later in the eastern Atlantic cities, crossed the American continent, crossed the Pacific to the Orient, and finally came back to Russia. In any geographical area the disease appeared suddenly and disappeared with comparative rapidity. It left in its wake sporadic cases which, however, for the most part have never become foci of new pandemics or epidemics. Rather, the residual organisms have become "opportunists," as Theobald Smith has expressed it, not producing acute epidemic disease, but appearing for the most part in sporadic cases or as secondary invaders. Pandemics are not very common.

Passing to diseases which are endemic, as typhoid fever, it will be found that there is a tendency for typhoid to become epidemic during certain years, that is to say, at irregular intervals typhoid fever increases either locally or generally. This same generalization is applicable to all endemic diseases, except the slow-growing diseases, as tuberculosis and leprosy. All endemic diseases, in other words, and those diseases which occasionally become pandemic, tend to wax and wane. More and more attention is being paid to the residual sporadic cases and bacillus carriers which are left in the wake of these epidemics, as it were, and which may be potent starting points of fresh outbreaks. Many instances are on record where such carriers have become foci for occasional subsequent epidemics, which at times have reached considerable proportions. Carriers do not necessarily spread disease.

The experiences with the summer diarrheas in Boston would suggest that there may be a somewhat similar epidemic tendency, a tendency for certain organisms to be dominant at one or another year. It was stated, for example, that in 1910 the dysentery bacillus was by far the most frequent organism found in severe diarrheas of children. In 1911 but few dysentery cases were found and the streptococcus became dominant. In 1912 neither dysentery bacilli nor the streptococcus were prominent, but the gas bacillus appeared to be the more important factor. And in 1913 dysentery, streptococcus, and gas bacillus cases were few in number and sporadic, while the capsulated bacillus appeared to be the most common etiological factor in the diarrheas.

There is one other feature of this epidemic tendency which deserves mention. It has been observed that late in the summer the type of organism met with in the diarrheas shifts somewhat, and the observations of four years' duration would suggest that the organism which will be dominant the next summer may, and not infrequently does, anticipate, as it were, the fall before, appearing somewhat abruptly in considerable numbers in atypical diarrheal cases as the season closes.

It is a well-recognized principle of epidemiology that the same organism does not produce acute disease year after year—experience has shown rather that epidemics are relatively short-lived, and that inter-epidemic periods are characterized as a rule by sporadic cases. The same explanation suggests itself in connection with the sequence of bacteria which appear to be causative agents in severe summer diarrheas. Although these diarrheas are of seasonal occurrence, the organisms associated with them do not reappear individually in epidemic proportions each year, but rather give way to other bacteria. It is impossible to predict the interval which will elapse between successive outbreaks of the same organism; the environmental conditions which may play a part in determining these outbreaks are also unknown. The reservoir from which these bacteria arise during epidemic years, and to which they may return to gather a fresh impetus as the outbreak subsides, is unknown, and the conditions which arouse these bacteria to activity are also unknown. Similarly, lobar pneumonia may be so prevalent at one or another year as to be regarded, and justly so, as epidemic; no one doubts the etiological importance of the pneumococcus in lobar pneumonia even when it is remembered that typical pneumococci are found in fully 30% of healthy throats, as "opportunists," during interepidemic years. Diphtheria bacilli are found in about 2% of healthy throats; this organism exhibits the same epidemic tendency as the pneumococcus, and strains which produce fully potent toxin may be isolated from mild sore throats, or from apparently healthy throats.

Carriers may be very important in this connection; an unexpected type of carrier has been met with in young children. Twins, aged six months, entered the Floating Hospital early in July, 1912, a year which was not a "dysentery year." These twins were not acutely ill; they were clinically mild feeding cases, and it was by accident that their movements were studied bacterially. During the eight weeks they were under observation one twin consistently harbored Shiga bacilli, the other twin Flexner bacilli. Neither gave evidence of bacterial disease. These patients would be regarded as unusually mild cases of bacillary dysentery when the facts are reviewed, and doubtless many similar cases would be discovered were careful systematic search made for them. The important point to remember is that precisely similar conditions may prevail

when any of the bacteria mentioned above "anticipate" the fall before the acute summer outbreak occurs. These atypical cases may provide a connecting link which sharply focuses the attention of the clinical and laboratory branches upon just the type of patient which in the past has led to confusion. In other words, the frank bacterial infection and the undoubted feeding case usually are recognized; the study of the doubtful and a typical case will be the most illuminating.

Whatever the final solution of the problem of the etiology of summer diarrheas may be, posterity alone can tell; the various theories will then be evaluated according to their worth, and the respect with which the present-day theories are regarded then will depend not only upon the results attained, but also upon the nature of the evidence on which these theories are based.

THE CLINICAL USE OF THE WATER MEAL IN DETERMINING THE SECRETORY AND MOTILE POWERS OF THE STOMACH.

By A. EVERETT AUSTIN, M.D., BOSTON.

Physician to Mt. Sinai Hospital; Berkeley Infirmary and Assistant to Boston Dispensary.

In an editorial in the *Journal of the American Medical Association*, No. 1, 1915, on water drinking, reference is made to the work of Carlson, Orr and Brinkman, as well as Bergeim, Reh-fuss and Hawk, on the direct influence of water in stimulating the gastric juice in the human stomach. From this we learn that water alone may induce a gastric juice whose acidity may be about 100 in less than twenty minutes after stimulation, during which time practically all of the water enters the intestine. They found that as much gastric juice was secreted, measured by its acidity, as after the Ewald test breakfast. Therefore, they claim that the water meal may be substituted for this. At the same time, when given on an empty stomach, one can demonstrate the presence of any food residue remaining from the previous day. Increased peptic power also follows the use of water.

They found that 500 c.c. of water leaves the stomach in ten to twenty minutes, and that 225 c.c. of gastric juice have been obtained from the drinking of only 50 c.c. of water. In their opinion small quantities of water produce greater stimulation than larger, and also the stimulation lasts longer. From their experiments, they consider that the acidities of 40 to 60, which are commonly accepted, are too low, and that in perfectly healthy individuals the acidities ran from 50 to 120, with an average of 77.

Based upon these experimental considerations, the clinical use of this water meal has been made by me in the men's medical clinic at the Boston Dispensary, and in the gastro-intestinal clinic at Mt. Sinai Hospital. The custom was to ask a patient to take a meal, the evening before, of meat, potato, bread, butter, rice and raisins, and then come to the clinic the next morning fasting. There 350 c.c. of water were given the patient and the contents of the stomach removed twenty minutes later, the extreme limit at which these authors claim that the water given has left the stomach.

The superficial advantages of this method were readily recognized: bread is not always available for the test breakfast, but water, of course, is. We can never rely on the time, if patients are allowed to take their bread at home and then come to the clinic; while, if taken in the clinic, a wait of 45 to 60 minutes is too long in a busy forenoon.

Water, too, as remarked by the before-mentioned authors, allows one to see readily whether there is any residue left from the Riegel meal.

This method, also, avoids a second introduction of the tube, which is necessary, if we first attempt to find food remnants in the fasting stomach, and then give the ordinary test breakfast.

Lactic acid, blood and bile are also much more readily detected in the absence of a mass of partly digested food.

The results of these examinations will be given as follows in a short table where the age, chief symptoms, acid values and diagnosis are included in parallel columns; in which we will first consider the functional forms of indigestion, which, as far as we know, are not ordinarily accompanied by marked changes in the secretory

and motile powers of the stomach; and then in a second table we will consider those forms which present a distinctly pathological process.

As is well known with the Ewald breakfast, the amount, which is ordinarily obtained, varies from 30 to 100 c.c. This factor, however, is of comparatively little value for several reasons; among these is the inability to remove all of the gastric contents either because the end of the tube is not below the level of the fluid or the gastric walls are in a state of myasthenia and do not possess the contractile force sufficient to eject the contents.

In my experience, a change from the erect to the supine position, helps but little. A bulb offers considerable aid when the stomach walls are weakened, but is, of course, of no assistance when the end of the tube does not reach below the level of the gastric contents.

When we compare, however, these amounts with those mentioned as a standard for the Ewald meal, we can see but little difference.

When an excessive amount is found, it may be attributed, of course, to two factors, either a hypersecretion in which the acid factors would be maintained or possibly increased, or to a lacking motility in which they would be diminished, owing to the retention of the original water taken into the stomach. The experimental evidence which we have deduced would show that a normal stomach empties itself of the water in twenty minutes; and, in these cases, when the amount has been found to be large, the acidities are maintained so that there is no probability of a retention of the original water.

This group includes apparently cases in which the secretory power of the stomach is not modified necessarily; such are ptoses, myasthenias, cholecystitis and constipation; hence it would

seem that we may take these acid values as a standard for the normal. True it is that no well person comes to a clinic for treatment, but many patients have vague gastric symptoms when no test will show any departure from the normal stomach.

The average, then, of these acid values, when calculated, is found to be 19 and 31, to be accurate, or, for comparison, may be regarded as 20 and 30.

When we compare these with the usual 30 and 60, as given for the Ewald breakfast, we find them distinctly less, instead of equal or greater, as was found by the authors quoted. The variations, however, of 15 to 53, are equally as great. Schuetz gives the difference between the free hydrochloric and total acidity, normally, as 20. Here, as would be expected, the average difference of 12 is much less. Two factors account for this: the absence of the neutralizing effect of protein and the salts of the bread. The difference which we actually do find, where no residue is present, depends on the mucus. This can readily be seen when we note the insistency with which the acid clings to floating masses of mucus when we attempt to neutralize them, reddened by Toepfer's reagent, with tenth normal sodium hydroxide.

We also note with this test meal a much greater frequency of the presence of bile. Apparently the gastric juice alone is not as effective in keeping the pylorus closed as is food. This may also be an explanation of the reduced acidity, as the duodenal contents apparently come through more easily.

Another explanation of the limited acidity may be the insufficient stimulus of the water.

We now come to those cases which present marked variations, in the amount of gastric contents and acid values, from those previously considered. They also offer unquestioned pathological changes in the stomach, which were demonstrated not only by the changes in gastric secretion and motility, but also by all the other means of diagnosis which we have at our disposal, including examination of the stools for occult blood and radiograms.

We will consider first three probable cases of ulcer which are designated as duodenal, and not gastric, because of the late appearance of pain

after food is taken, and as ulcers rather than pure nervous hypersecretion, if such exists, on account of the presence of occult blood in the stools. There is a marked increase, as noted, in the amount in two cases to 110 and to 180; while none is observed in the other, 50.

There is also an increase in the acids of two cases and not in the other. When, however, we find the product of the amount withdrawn and the total acidity as factors, which is allowable, since practically all of the total acidity is due to hydrochloric acid, we find that this result is increased in all cases above what is usually found.

It seems a matter of indifference whether we find a normal amount with high acid value or a large amount with increased or normal acid value: the interpretation is always the same—hypersecretion—when the product of the factors is more than 2000. In these deductions some may object that there is gastric juice in the stomach when the water is given, and that the former is not due to the stimulus of the water, but the significance is the same as continuous secretion is but an exaggerated form of hypersecretion.

Two of these cases show an absence of hydrochloric acid; in other words, are typical achylas. Associated with them, too, are the small amounts of gastric contents removed, as is also found when the Ewald meal is used. Whether in these particular instances bread would prove a greater incentive than water alone, was not determined; that is a matter for further investigation. The largest amount of content found, 250, was observed in connection with food residue showing an apparent pyloric stenosis.

The cause of this stenosis was not determined, but did not appear to be malignant. In the only probable case of gastric cancer, though no mass was felt, the amount was large, 100; but the acids fell to 9 and 15 while lactic acid was present.

After this comparatively limited use of the water breakfast, it would seem to serve all the needs of a clinic for establishing secretory and motile powers of the stomach.

This report, nevertheless, is to be regarded only as a preliminary one, and its employment will be continued until its worth is disproved or firmly established.

POSTERIOR GASTRO-ENTEROSTOMY BY EXACT MEASURE.*†

By M. P. SMITHWICK, M.D., BOSTON.

For seven years past I have done posterior gastro-enterostomy occasionally, always following as closely as possible the conventional technic, but never wholly without apprehension lest there be some degree of kinking from anastomosing parts which wouldn't lie quite easily and naturally together. As I wasn't troubled over other possible mishaps, it seemed to me that, whether my fear of kinking was reasonable or unreasonable, it should be possible to remove it by some system of accurate measurement. From time to time I have tried to put such a scheme in practice but never satisfactorily until my last three (now four) cases.

To distinguish it from "no loop" and "short loop" let us style as normal the operation in which stomach and jejunum are anastomosed as they lie easily together without tension, the length of jejunum being that required for the anastomosis without suspending either organ on the other.

According to the conventional technic, one embraces in a clamp a portion of the jejunum high—as high as possible for a no-loop operation and within three inches of the top for a short loop operation. He embraces in another clamp a fold of posterior stomach wall extending from a selected point at the bottom of the stomach upward, in whatever direction he wishes the jejunum to take and anastomoses the two portions. The point is that a portion of jejunum pre-determined or selected by guess is anastomosed to the portion of stomach thought to be most favorable for drainage, but without any accurate measurement to determine whether in the given case the latter will fit perfectly to its outlet. This veritable missing link in the technic may account for some of the "inherent defects" of the operation.

In the plan which we are trying to follow, the posterior wall of the stomach having been exposed through a generous opening in the mesocolon, the omentum, transverse colon and stomach are held in the left hand with the left thumb in the slit in the mesocolon. While the upper part of the jejunum in its natural position within the abdomen is straightened out by the right hand in the desired direction, the exposed posterior wall of the stomach is laid upon it without any tension in any direction. At the point where the posterior aspect of the greater curvature of the stomach comes in contact with the jejunum a stitch is placed in each organ. A second stitch is placed in the jejunum three inches higher up. All three stitches are cut long. The points of artery clips on the first two

stitches are brought together and another stitch is placed in the stomach where the upper stitch on the jejunum comes in contact with it. If one prefers he can make the lowest part of the stomach as it lies within the abdomen or some other point along the greater curvature the starting point for this determination. According to the first plan one decides on the direction of the jejunum, and then the proper site for the anastomosis is the lower three inches of the line of contact of posterior stomach wall and jejunum. If this direction doesn't allow enough jejunum, make it more oblique. If an oblique position gives more jejunum than desired, make it more vertical. If there is no special reason for giving the jejunum a particular direction, one corresponding to the opening in the mesocolon may well be chosen as most convenient. According to the second plan one selects a point on the stomach wall which is to be the lower end of the anastomosis, and makes the jejunum conform to that without tension. The basic idea of this scheme is accuracy. It is intended to eliminate all inaccuracies of application, including torsion, flexion, and also suspension of stomach on jejunum, or the opposite. In cases without obstruction before operation, faulty application sufficient to cause symptoms of blocking should cause them at once. At least a part of the late symptoms of blocking commonly attributed to the inherent defects of gastro-enterostomy are due to faulty application, these symptoms appearing as the original obstruction disappears. In the same case a no loop operation may be either a perfect application or a suspension of the stomach or jejunum, according to the direction given the jejunum. A perfect application insures the proper length of jejunum, but that the converse is not true one can easily convince himself. By following this scheme advocates of the no loop operation can at the same time avoid torsion, flexion and suspension. Without some system of measuring, one cannot entirely exclude one or more of the varieties of misapplication. No detail that makes for accuracy should be omitted. This applies particularly to cases without obstruction or those in which as a result of operation the obstruction may disappear.

Of the three (now four) cases in which this plan was followed, each was x-rayed before operation and in each instance we found at operation frank duodenal ulcer confirming the pre-operative diagnosis. In the first, a case of Dr. G. C. Mahoney of Somerville, operated on Oct. 22, 1914, with Dr. Mahoney's assistance, and in the third, a case at the Soldiers' Home, operated on Dec. 31, 1914, the measurement was begun by deciding which direction the jejunum was to take. This gave a two and a half inch jejunal loop in one and none in the other. In the second case, operated on Dec. 28, 1914, with Dr. E. P. Starbird's assistance, the point where the greater curvature of the stomach crossed the jejunum as at first held was within three inches of the top of the jejunum so that we then se-

* Abstract in part of a paper read February 11, 1915, at a clinical meeting of the Mt. Sinai Hospital under the title: "Notes on the Technic of Posterior Gastro-Enterostomy, and on the Study and After-care of Gastro-Intestinal Cases with Symptoms of Obstruction."

† Received on March 17, 1915, for publication.

lected another point on the greater curvature (in this instance the lowest point) which would allow three inches of jejunum for anastomosis when the latter was straightened out to that point without tension on either organ. In the fourth case, operated on February 27, 1915, with Dr. Starbird's assistance, the abdominal wall was very thick, and for ease of manipulation a point on the greater curvature was selected nearer the pylorus than would otherwise have been chosen. This gave more jejunum and still was the correct length to reach without tension, the point selected.

It was very interesting and rather surprising to me to realize that even in the first case in which this scheme was tried my fear of a misfit had entirely disappeared. We are keeping detailed records of all symptoms of stasis from the completion of the operation as a basis for determining later whether in a series of cases this plan is an aid toward uniformly perfect results.

PROGRAM AND DIRECTIONS FOR THE MENTAL EXAMINATION OF ASOCIAL, PSYCHOPATHIC AND DOUBTFUL SUBJECTS.

BY ROSE S. HARDWICK, BOSTON,

Instructor in Education, Boston School of Physical Education; formerly Assistant in Psychology, Psychopathic Hospital, Boston.

(Continued from page 821.)

THE HEALY TESTS.

Most of these tests are treated very fully in the descriptive monograph,⁷ but for convenience some of the principal facts in regard to them are summarized here. The age limits given are only approximate.

I. For young children (4 to 8 years), and subjects of doubtful mentality. The minimum number of moves is eleven. Usually not more than five minutes need be allowed. The character of the errors is more significant than the time. Several distinct levels of performance are found.

1. The pieces are put on the board, but no effort is made to fit them into the holes.

2. The blocks are put into the holes, but without trying to fit them. Sometimes they are put in obliquely, or on edge.

3. The subject tries to fit block to hole, but by the trial and error method. The same errors are repeated, and final success is a matter of time and chance.

4. The subject considers the shape and size of each piece, and attempts to choose the appropriate hole. These individuals generally learn by experience and show less tendency than the preceding group to repeat errors.

5. A few study the picture, decide what is needed to complete the meaning as well as to fit a given hole, and then select the appropriate piece. These subjects make few errors and rarely repeat an error.

It is noteworthy that comparatively few consider anything except the size and shape of the pieces, and those few are scattered among all ages and many grades of mentality.

The reaction to the double triangles constitutes almost a test by itself, and frequently appears to be determined by affectivity rather than by intelligence. The problem is complicated by the fact that the large triangle is nearly, but not quite, equilateral. Hence a subject with some knowledge of geometry and a fairly well trained eye may be more readily discouraged by it than a subject of distinctly poorer mentality and less training.

II. (5 to 8 years.) Minimum number of moves, 13. Time, not more than 5 minutes. As this is somewhat more difficult than the preceding it usually need not be given to those who fail badly on No. 1, that is, those at the first and second levels mentioned.

III. (From 8 years.) Minimum number of moves, 5. Time, generally not more than 5 minutes. It has been done by children of 12 years in 12 seconds. The examiner should record the number of moves, of repetitions of errors, and of obvious impossibilities tried. It is convenient to record each move by a pencil stroke. Obvious impossibilities may be indicated by crossing the stroke (x) and repetition of errors by a double stroke (v).

IV. (From 10 years.) Minimum number of moves, 11. Time, from 5 to 8 minutes. It has been done by children of 12 years in 1 minute. This is more difficult in some respects than III, but it is sometimes solved by subjects who fail on III. The record may be made in the graphic form described by Dr. Healey, or as suggested above for III.

V. (From 12 years.) Minimum number of moves, 6. Time, not more than 10 minutes. Children of 12 years have done it in less than 2 minutes.

VI. (From 6 years.) Time of exposure, 10 seconds. This test takes but little time with the younger and more defective subjects. Their own recital is brief, and few questions are needed to discover the limitations of their memories and the degree of their suggestibility. The more intelligent ones give longer recitals, and more questions are required for them, but the value of the data obtained is proportionately greater.

Important facts to bring out in the report are: (1) fullness and accuracy of memory in free recital, (2) improvement or the reverse under questioning, (3) degree of suggestibility, and (4) any peculiarities in the type of reaction as, for example, the tendency of some subjects to ramble on indefinitely with imaginative details following chance associations.

VII = Y 16 = B X 2.

VIII. (From 7 years.) The number and kind of errors is more important than the time. A subject who understands the question generally responds promptly.

IX. (From 12 years.) It is convenient to use this and the following as introductory to B XV 3.

X. (From 13 years.) This should not be given to subjects who fail entirely on IX.

XI = B XV 3.

XII. (From 9 years.)

XIII. (From 7 years.)

XIV. (From 14 years.) Time, not more than 3 minutes. This is a vocational test. It should never be given to a subnormal.

XV = B XV 4.

XVI. (From 12 years.) At 12 years, from 65 to 75 squares should be tapped in the 30 seconds, with from 0 to 4 errors. This is good as a vocational test. If time permits, from 3 to 5 trials should be given to show the effect of practice.

XVII, XVIII and XIX are not usually given as separate tests.

XX. This is valid from 12 years, but only for subjects who are familiar with the game. For lack of time it is rarely given.

XXI. (From 9 years.) The responses should be recorded in full.

XXII. (From 9 years.)

XXIII. (From 9 years.) From 5 to 10 minutes is usually sufficient. The longer time generally goes with the poorer results.

This is a pictorial completion test, sometimes called the "pictorial Ebbinghaus," or the "apperception test." Dr. Healy added it to his series after the publication of the monograph. It may replace or supplement the prose completion test, and is valuable for subjects too young or too defective to use the verbal narrative, as well as for illiterates and non-English speaking individuals.

The test consists of a picture puzzle representing ten incidents. From each of these ten parts of the picture is cut a square containing something necessary to the sense. For example, one boy has just kicked a football to another boy, and the ball is on the square cut out. Of the same size as these squares are still others, some of which are blanks, while some show a variety of objects not appropriate for filling the spaces.

The puzzle is placed before the subject, with the blocks (right side up) at his right. The examiner points to the cart from which a wheel has come off, and says, "What has happened here?" The answer usually comes promptly, "The wheel has come off." "Very well, now see how quickly you can find the wheel and put it in place." As the wheel goes into position, the examiner starts the stop-watch and begins his record. When the subject seems to have finished, he is told to look it over carefully and make any changes that he likes. The time is taken when he says that he is satisfied. It is

well then to ask him to explain the picture. This may lead to his making corrections (which should be recorded as such), and it enables the examiner to decide how far any of the blunders were logical.

A specimen record is here given.

Time 4 minutes, 47 seconds.

For wheel put wheel

" cat " milk bottle, daisies, crow

" broken window put whole window

" football " baseball

" hat " hat

" log " ax, log

" white bird " cage, crow, white bird

" apple " dish of fruit, cherries, apple

" rooster " cat

" dog " dog

The three errors, in this case, were not illogical for the subject explained that the girl was feeding the bird, and that the rooster was afraid of something, and he thought the cat was the most probable of the objects represented.

The errors in this test show very distinct types.

1. Imperfect apperception, as above.
2. Association by similarity instead of logical meaning, as when ax is substituted for log.
3. Fantastic interpretations, as when the clock is put where the hat should be because "the girl might want to know the time."
4. Fatigue, when a few blocks are well chosen and then the remaining places filled with blanks
5. Apperception lacking, when the spaces are filled with any blocks that come to hand, and no attempt is made at explanation.

THE KNOX SCALE.

This scale has been developed at Ellis Island for the examination of illiterate aliens.⁸ It resembles the Binet Scale both in being an age scale, and in having adopted, with little or no modification, many of the Binet tests. The tests not represented in either of the three sets already discussed fall into four principal groups.

1. Information tests, III 1 and 5, VI 5 and 7, VII 6, VIII 4, IX 5 (second part), X 6, XI 4 and 5, and Adult (make-up) 5 and 6. These are similar to the Binet "information" tests, but are suited to a different environment.

2. Arithmetical tests, X 4 and 5, XI 6, XII 5 and 6, and XIII 6. These are concrete operations and do not presuppose any formal education.

3. Performance tests, IV 1 and 2, V 1 and 2, VI 1, 2 and 3, VII 1, 2 and 3, VIII 2, IX 1 and 3, X 1 and 2, XI 1, XII 1, XIII 1 and 2, and Adult (make-up) 1, 2 and 3. These resemble the Healy puzzle tests.

4. Miscellaneous tests, V 5, XI 3, XII 3, XIII 3, and Adult (make-up) 4 and 7.

Some of these tests might be classified differently, as, for example, VIII 4 and XI 4, which are comparisons of remembered objects, and similar to Y 9 = B VIII 1, though not its equivalent.

Two of these tests call for further consideration.

The Seguin form-board (Norsworthy's modification) which appears as K IV 1, V 1 and IX 3, has been specially studied by Goddard.⁶ He found that for normal subjects between the mental ages of four and twelve years the time ranged from about 34 seconds to 14 seconds, while the low-grade defectives (mental age, four years) sometimes took more than 76 seconds. His figures indicate that for both normals and defectives, the time decreases quite regularly with increasing mental development. This being the case, there seems to be no need of limiting the use of this test to particular years.

The number and character of the errors is also significant and Goddard suggests a form of record similar to that above described for H XXIII. The board is placed before the subject with the longer dimension from right to left, and so that the cross is at the top and the star at the bottom. The blocks are denoted by numbers from left to right along each line (for example, the cross is 1; triangle, 2; circle, 4; star, 8), but these numbers do not appear on the board or on the blocks. The record occupies ten lines, one for each block. Thus, if the first line reads 6 9 3 5 6, it means that block (6) was tried first in hole (9), then in (3), then in (5), and finally in its proper place. If no mistakes are made, the record appears as a single column of figures, the order of which shows the order in which the blocks were taken.

K adult 7, the ink-blot imagination test, should be particularly serviceable because the six ink-blots used by Knox⁹ are well chosen to present varying degrees of difficulty, and because this material has been standardized. Three groups of subjects were tested.

- (1) 25 average Italians, 15 to 30 years old.
- (2) 25 defective Italians, 15 to 30 years old.
- (3) 12 American men of common school education, 25 to 35 years old.

The following facts were ascertained, by the aid of which the examiner may interpret his results.

I. Failures to find resemblances occur.

- 17 times in 150 in group (1)
- 80 times in 150 in group (2)
- 0 times in 72 in group (3)

II. Illogical associations are characteristic of defectives.

III. The average reaction-time is, for normals about 3.7 seconds, and for defectives about 6.3 seconds.

(See also W 45.)

MISCELLANEOUS TESTS.

1. Labyrinths, B and A (from 13 years). B is the more difficult for most subjects.
2. Cancellation, the A-test (from 13 years) W 26.

3. Dot-counting (from 13 years) W 27. Compare K adult 4.

4. Substitution (from 14 years) W 37. This is similar to H VIII, but more difficult.

5. Prose completion (from 14 years) W 48. The form of this test, which has been used most in the hospital work, is a short fable.

6. Ethical discrimination (from 13 years). Serial arrangement of ten offenses. This is adapted from Dr. G. G. Fernald's test.⁷ The two sets, one for boys and one for girls, now in use at the Psychopathic Hospital, were prepared by Dr. V. V. Anderson.

PRELIMINARIES TO THE EXAMINATION.

Certain matters preliminary to the mental examination proper deserve careful attention. They consume but little time in practice, whereas the neglect of them leads to serious waste of both time and effort, with, too often, inferior results.

THE ATTITUDE OF THE SUBJECT.

The importance of putting the subject at his ease and of winning his confidence to some degree will bear emphasis here, and a few practical suggestions may be helpful to the inexperienced examiner.

School children examined at school and inmates of an institution examined in that institution have the advantage of a familiar environment. If, in addition, the examiner happens to be a member of the regular staff, the subject is likely to respond promptly and naturally.

In a hospital, on the other hand, the conditions are less favorable. Especially in the out-patient departments, the subject is likely to find himself in unfamiliar surroundings, and, if he recognizes the nature of the institution, he may be distinctly apprehensive.

The younger subjects and those more deficient mentally often appear to be quite uninfluenced by the nature of the institution. They may, however, be timid in a strange place or with a strange person, and in extreme cases it is necessary to have a parent or friend present during the examination. This is undesirable, and should be avoided if possible, for the presence of a third person tends to distract the subject's attention, and frequently a well-meaning friend interposes with suggestions and explanations in such a way as to destroy the significance of the tests.

Usually the pleasantly spoken invitation, "Will you come with me for a while?" or, with children, "Come and play games" is sufficient. Sometimes the sight of a game or puzzle helps. Things of no importance in dealing with children accustomed to kindness and gentleness may carry unexpected weight with those who are fearful and suspicious. Some who shrink from a direct approach, if given opportunity to watch

the examiner for a few minutes as he moves about the room and talks with others, will go with him of their own accord.

Older and more intelligent individuals, as well as those who have already had the medical examination, are sometimes very nervous and apprehensive. An apparently trivial thing which, however, may do much to reassure the subject is to enter the examining room slightly in advance of him, and courteously but casually ask him to close the door. Psychologically there is a great difference between being shut into a strange room at the mercy of a strange "examiner," and shutting that same door oneself.

An intelligent subject may find many of the tests childish and be inclined to resent them. His coöperation can generally be secured by explaining that the tests are merely devices for getting acquainted with his individual needs and capacities, and that easy tests serve this purpose quite as well as more difficult ones and require less time.

The more mature subjects sometimes display anxiety as to whether they are "failing" or "passing." In that case, it should be explained that this is not like a school or civil service examination. We care quite as much to understand the nature and extent of the subject's difficulties as to gauge his abilities. So if he does his best with each test it is sure to be "right."

In this connection it should be said that, while logically the medical examination should precede the mental, practically the task of the psychologist is likely to be easier when the reverse order is followed.

SENSORY TESTS.

Since the ordinary mental tests depend so largely upon sight and hearing, it is important for the examiner to know whether his subject is handicapped in either of these respects, and, if so, to what degree. Sometimes it is evident at once that both these senses are acute, or that one or both are defective. If the "history" has been taken, or if the medical examination has preceded the mental, or if the subject is a child brought in by parents or guardians, definite information may be obtainable from these sources. An apparently casual question, such as "Do you have headaches?" or "Did you ever wear glasses for reading?" will sometimes elicit the facts desired. In many cases the results of such inquiries are negative; but just when the examiner is making up his mind that they are needless, and that, for once at least, the pressure of work justifies their omission, there appears the exceptional case. Perhaps it is a small boy who blunders cheerfully through the examination, and at its close pulls a pair of spectacles from his pocket, remarking that he is supposed to wear them but never does so. Or a girl admits that glasses have been prescribed for her, but because a little brother's eyesight was seriously injured by the breaking of his glasses, her mother is unwilling for her to wear them.

The examiner must, therefore, be cautioned to be always on the watch for visual or auditory defects. As a direct result of such the subject may react in specific tests with the slowness and inaccuracy characteristic of low-grade mentality. Furthermore, it is now recognized that some sensory defects involve a nervous strain which may lower the general level of mental efficiency.

If there is reason to suspect sensory disorder, the subject should be referred to a specialist, oculist or aurist, as the case may be; but, for his own purposes, as a means to the correct interpretation of tests, the psychologist may occasionally wish to give rough tests of sensory capacity.

A little practice will enable him to give the whispered speech test (W 18 A), or the watch test, for hearing, well enough to check, or to supplement, his information.

For visual acuity, Franz's³ test is well adapted to small rooms. This consists of a card on which are shown two parallel lines, 1 mm. apart and each 1 mm. wide and 3 mm. long. Franz used white lines on a black card. They should be distinguished as two at a distance of from two to three meters. It is convenient to hang the card on the wall opposite the window, hanging over it a blank card. Let the subject stand by the window facing into the room; remove the covering card and ask what he sees; let him approach, if necessary, one step at a time, until he distinguishes two lines; then let his eyes be covered in turn by means of a small card, and ascertain whether he sees equally well with both; if not, let him approach nearer until the lines appear separate to the poorer eye also, thus arriving at some notion of the difference between the eyes. For purposes of checking, it would be well to prepare two test cards, the lines being vertical on one and horizontal on the other, and to expose these cards in irregular order.

Lack of space, as well as lack of control over lighting and noise make it out of the question to use most of the standardized tests, or to compare results readily with those of other examiners. The tests used must be standardized for the occasion, and can be relied upon only within very wide limits.

THE NATURE OF THE PROBLEM.

Better results will generally be obtained, and at less cost of time and effort, if at the beginning of an examination the examiner informs himself as to the problem involved. By this is meant the immediate occasion for the examination as stated by the subject himself, or by his friends or guardians.

Some examiners dislike to receive such information in advance, preferring to approach each case in perfectly naive fashion. This attitude is, in its way, thoroughly scientific and, as such, defensible if time does not press. In some instances lack of information compels it. As a

rule, however, it probably does not make for efficiency.

The real danger, against which such an attitude expresses an extreme precaution, lies in the tendency of the inexperienced examiner to take this first statement of the problem as a definite indication of its source. He should be warned emphatically that there is no necessary relation between them. He must be prepared to see the case transformed under his eyes, and that, not occasionally, but frequently. What he does obtain from the original statement of the problem is a notion of the practical issues already involved, in the light of which he can interpret the results of his examination more readily and more adequately, and decide more wisely as to the number and character of the supplementary tests to be given.

It is true a case is sometimes misrepresented—rarely, with deliberate intention, more often, quite unconsciously. For instance, a boy of about thirteen was brought for examination. He was a state ward. One of his sisters was feeble-minded, and it was feared that he might be deficient mentally. The people with whom he was living reported, among other things, that his memory was abnormally poor. In the course of the examination, however, he gave a fluent and vivid account of a moving picture play, with a rather complicated plot, which he had seen on the preceding day. Inquiry brought out the fact that the things for which his memory was so poor were his household tasks, such as fetching the fire-wood and feeding the hens. It is true that he was immature, but it was his imagination and not his memory that was undeveloped. He had failed, that is, to appreciate the point of view of the housekeeper and of the hens—but so, for that matter, had his elders failed to appreciate his point of view.

(To be continued.)

Clinical Department.

A SUGGESTION IN THE TREATMENT OF HEMORRHAGIC DISEASE OF THE NEW-BORN.

By J. C. HUBBARD, M.D., BOSTON.

IN hemorrhagic disease of the new-born, we know that subcutaneous injections of rabbit serum are of definite benefit. Recently come reports that subcutaneous injection of human blood will bring about cures. By these two methods some substances which the baby lacks are provided in small amounts. These substances are absorbed and the hemorrhages cease. It has been shown clinically so many times

that human blood given to the baby by transfusion is the best treatment, that there is no longer any discussion on this point. Transfusion has saved some babies when other methods have apparently failed. I do not know whether transfusion of human blood is the best treatment because the dosage is larger or because the substances are different. Clinically it does not seem to me that the difference in the effect of an injection of rabbit serum and a transfusion is due to the rapidity of absorption, though, of course, by the later method the lacking substances are mixed with the blood at once.

We all appreciate the difficulty in the technique of transfusion in the new-born because of the small size and delicacy of the baby's veins. To transfuse a baby light anesthesia is necessary to keep the baby quiet and care must be taken not to give the blood too rapidly or in too large a dose.

The suggestion I wish to make, and I make it before I have been able to carry it out myself, because it may be some time before I see a proper case, is that the blood be put free into the abdominal cavity of the baby. If Kimpton's tube were used, a hole in the abdominal wall only large enough to admit the cannula would be necessary. The blood could be run in rapidly and there would be less danger of an over-dose. The hole could be closed with a stitch or two. The whole operation on the baby would require but a few moments. Less anesthesia would be necessary. The necessary exposure and the operation itself would cause certainly no greater shock than a dissection of the jugular vein, and I believe absorption from the abdominal cavity would be sufficiently rapid to cure. It certainly would be as rapid as the absorption of rabbit serum from under the skin, which in the milder cases is curative.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SECTION OF MEDICINE.

STATED MEETING, FRIDAY EVENING, FEBRUARY 26, 1915. DR. JAMES E. TALLEY, IN THE CHAIR.

THE VON NOORDEN TREATMENT OF DIABETES MELLITIS.

DR. JAMES TYSON: I have selected this subject because the administration of the newer dietetic treatment for which we are largely indebted to von Noorden has resulted in a complexity, trying to doctor and patient, and I thought I might be of service in simplifying it. It will aid me in my purpose to follow Naunyn and v. Noorden and subdivide diabetes into three rather arbitrary divisions. (1) Slight or mild cases; (2) transitional or semi-

severe; (3) really severe cases. There are many mild cases which may be so controlled that the patient is practically as well off as if there were nothing the matter. v. Noorden claims that not enough stress is laid on the requirement that to insure success sugar must be kept permanently absent from the urine and even transitory reappearance must be avoided if possible. Treatment consists in the strict elimination of carbohydrates from the food. This rests the "sugar factory" and gives opportunity for recuperation and resumption of function. When sugar is not removable by simple carbohydrate diet v. Noorden resorts to reducing the proteins in addition to cutting out the carbohydrates and to employing the so-called "oatmeal cure" as an additional measure. In these cases brilliant results are sometimes obtained by interposing periods of diet composed exclusively of oatmeal or some similar food accompanied and followed by two or three days of vegetable food and eggs. For never more than three days in succession should the oatmeal diet be used. "Fats are burned in the fire of the carbohydrate" is a statement not altogether correct, but one which emphasizes the fact of the dependence of acetone metabolism upon carbohydrate metabolism. Alkalies and especially sodium bicarbonate, neutralize but do not prevent the production of acetone, diacetic acid and oxybutyric acid in the blood. v. Noorden gives one-half oz. to two-thirds oz. of sodium bicarbonate in a day. I seldom give more than a drachm or a teaspoonful three times a day. In nearly all cases in the presence of decided acidosis I give them nearly continuously. The citrate of potassium and sodium are more palatable than the carbonate and are less disturbing to the stomach. In the diet in incipient coma all restrictions except pure sweets are removed. The free use of milk, 6 to 8 oz., every two hours is recommended by some. If obtainable sugar-free milk may be used. v. Noorden claims that he has tided over cases by an exclusive diet of oatmeal preparations. He advises no food, but large quantities of whiskey well diluted 3 to 5 oz. daily. These alcohol periods are continued for one to two days followed by milk and oatmeal soups with a gradual return to the diet of chronic diabetes. Opium, chloroform and ether increase the acidosis. Medicines in the earlier stages of diabetes have little value and less in the latter stages. Certain mineral waters have a reputation. Their operation is probably similar to that of the sodium carbonate already described. They should be taken freely. An important measure in the treatment of diabetes is rest, especially in bad cases. Efficiency is easily shown by urinalysis before and after a rest of a couple of days in bed.

THE DIAGNOSIS OF ENTEROLITHS BY MEANS OF THE ROENTGEN RAYS; WITH REPORT OF A CASE.

Illustrated by lantern slides.

By DR. GEORGE E. PFAHLER AND DR. C. J. STAMM. (Read by invitation.) The paper is a report of a case of an enterolith of about one and one-half inches in diameter, which was first recognized as a movable body in the abdomen, and thought to be a movable kidney or a mesenteric gland. By Roentgen examination it was determined to be an enterolith, located in the cecum and capable of moving from the pelvic cavity to the crest of the ilium. By

the use of glycerine and olive oil enemata and abdominal massage it was moved from the cecum to the rectum and then removed by the finger. It is claimed to be the first case to be diagnosed before operation or autopsy, and the first large enterolith to be removed without operation.

STUDIES IN RENAL FUNCTION WITH SPECIAL REFERENCE TO NON-PROTEIN NITROGEN AND SUGAR CONCENTRATION IN THE BLOOD, PHENOLSULPHONEPHTHALEIN ELIMINATION AND BLOOD PRESSURE.

DR. A. H. HOPKINS (by invitation) and DR. LEON JONAS (by invitation). The purpose of this paper is to study:

1. The relation of proteid feeding to nitrogen retention in the blood.
2. The relation of nitrogen retention to renal function.
3. The relation of blood sugar, blood pressure, phthalein elimination and nitrogen retention. So far as we can ascertain, there have been no studies covering all of these phases simultaneously and the possible relationship existing between them; though quite recently Folin and Frothingham and Smilie have reported upon somewhat similar studies, the latter's production having been published shortly before the completion of this work.

From our studies we have reached the following conclusions:

1. Proteid feeding in nephritis has a direct influence upon the retention of nitrogen in the blood. This is most pronounced in the pure chronic interstitial type with hypertension.
2. The estimation of retention by blood analysis is of definite clinical value from the standpoint of therapy, and though this series is too limited to permit of definite conclusions in regard to its prognostic value, our findings so far confirm those of other workers who advocate its usefulness in this field.
3. Chronic passive congestion does not cause an increase of waste nitrogenous products in the blood.
4. In the presence of nitrogen retention, the phthalein output is usually low and the blood pressure frequently high.
5. Chronic passive congestion may greatly impair the phthalein output. Variation in the elimination of this dye may also be noted in different stages of nephritis, and in cases with "hyperpermeability."
6. To be of value, the nitrogen retention and phthalein tests should be repeated at intervals, the value of the former being increased when combined with clinical observations of the patient, diet, etc.
7. A slight hyperglycemia occurs in many high pressure nephritides and frequently in those with retention of nitrogen and impaired phthalein elimination.

PECTORAL ABSCESS.

DR. DAVID RIESMAN: Attention is called to subpectoral abscess as an important clinical condition. The onset is acute with intense pain below the clavicle. A focus of entrance of infection may or may not be present. The fever is high, the nervous symptoms are marked and leukocytosis is present. Two illustrative cases are cited, in both of which the streptococcus was isolated in pure cultures from the pus. Treatment consists in early incision.

SPLANCHNIC NEURASTHENIA AND ITS TREATMENT.*

DR. A. B. HIRSCH: The fact that the protean symptoms of true neurasthenia can be removed by one generally applied method, mental calm with muscular inaction (the Weir Mitchell rest cure, in practical shape) is now everywhere accepted. That patients with neurasthenia associated with overdistention of the intra-abdominal veins need radically different treatment is not, however, as widely known as the relative frequency of their occurrence would seem to suggest. Three cases are cited exhibiting a type of neurasthenia in which abdominal muscular relaxation coexists and largely depends upon splanchnic venous congestion. Unless correctly differentiated and treated such patients pass into hopeless invalidism. This type of neurasthenia improves coincidentally with increased tone of the splanchnic vessels and treatment is essentially that by physical methods in suitable combination. In the first case, which was that of an unmarried woman of 40 years presenting a typical instance of splanchnic neurasthenia with possible complication of incipient pulmonary tuberculosis, a preliminary course was given of the static wave current with an 8" x 10" electrode applied to the upper abdomen. This sought the local contractile action upon the relaxed abdominal organs and tissues as well as the general tonic effect by exercise of unstriated muscular fiber everywhere. This alternated, through vibrassage of definite vertebral areas, with reflex action upon the affected organs. Contraction of the distended liver (the "liver reflex" of Abrams) was attempted by applying a double-prong vibratode upon the first, second and third lumbar intervertebral spaces. By a like application below the seventh cervical vertebra the general vasomotor apparatus is stimulated. For increasing the tone of the splanchnic vasomotor system vibrassage of the intervertebral spaces from the second to the eighth thoracic vertebra inclusive was given. Later the rapid sinusoidal current was substituted. To improve the power of the abdominal wall muscles sponge electrodes were held beneath each lower scapular angle, the slow sinusoidal current being in action. To redevelop normal action of the intestinal muscular layer, its peristaltic action was imitated by the slow sinusoidal current. This modality may require the addition of the static induced current. Relief was noted at each visit and fair progress has been made. The symptoms and treatment in the second and third cases presented marked similarity.

ADDISON'S DISEASE IN A NEGRO WITH INVOLVEMENT OF THE CENTRAL NERVOUS SYSTEM.*

DR. ALFRED GORDON: The case is that of a middle-aged mulatto who developed during 18 months the following symptoms: An exceedingly dark face, very dark dorsum of hands and feet and dark bluish spots on the mucous membrane of the mouth and pharynx. The darkened areas had the color of coal and contrasted strikingly with the rest of the skin. At the same time he presented marked asthenia, diarrhea, vomiting and vertigo. He also showed cerebellar phenomena, namely,—asynergia, loss of knee jerks on one side and much diminished knee jerk on the other side. The blood was normal; Wassermann negative; urine negative. Temperature

96.5; blood pressure 80-100. Autopsy showed calcareous masses in the apices of the lungs, thickened mitral valves, adhesions around the spleen, liver and pancreas. The suprarenal bodies were unusually large and under the microscope their tubercular nature was demonstrated. The cerebellum presented a softened area near the middle line in one hemisphere. The spinal cord from the midthoracic down to the lumbar segment was surrounded by inflamed pia, especially at the level of the roots; the posterior roots showed degeneration. The direct cerebellar tract and Clarke's column of cells on one side did not take stain as well on one side as on the other. The paper discusses the relationships between all these findings. The cord lesions corresponded to the level from which the sympathetic system sends out fibres to form the suprarenal plexuses. The conclusion is reached that the adrenals formed the point of departure of the entire morbid process. A plea is made for post-mortem examination of the nervous system in every case of Addison's disease. The occurrence of the disease in a negro is a rare phenomenon.

Book Reviews.

The House-fly. By C. GORDON HEWITT, D.Sc., F.R.S.C., Dominion Entomologist of Canada. Cambridge, England. University Press. New York: G. P. Putnam's Sons.

This monograph in the Cambridge Zoological Series is devoted to an exhaustive study of the common house-fly, *Musca Domestica* Linn., its structure, habits, development, relation to disease and methods of control. Parts of it have already been published in the *Quarterly Journal of Microscopic Science*, but the present volume represents an entirely new work incorporating the contributions to the knowledge of the subject which have been made during the past five years. The volume is not a popular treatise, but is primarily intended for the use of entomologists, physicians, students, health officers and others similarly engaged or interested in the subject. The text is divided into six parts, dealing respectively with the anatomy and bionomics of the house-fly, its breeding habits and life history, its natural enemies and parasites, other species of flies frequenting houses, the relation of house flies to disease, and preventive and remedial measures for their control. The volume is abundantly illustrated with 104 excellent figures, some of them colored, and concludes with a profuse and valuable alphabetic bibliography.

* This paper was read at the January Meeting of the Section on Medicine.

THE CONTROL OF OCCUPATIONAL DISEASES.

IN England the study of this class of diseases was initiated by Sir Thomas Oliver, who found that a large proportion of persons employed in the pottery industry became seriously affected with lead poisoning, and it was subsequently ascertained that there are no less than 150 trades in which poisoning by lead is a hazard. In this country much attention has been given during the past few years to the study of occupational diseases, with a view to preventive legislation, and the first American congress on the subject was held in 1910, in Chicago. Dr. J. B. Andrews made an investigation of phosphorus poisoning, which led to legislation controlling the match industry, and many other important investigations have since been set on foot, such as those by the United States Labor Bureau, the Health Boards of Massachusetts and New Jersey and the New York and Illinois State Factory Commissions. The practical results, however,

are as yet inadequate, and much painstaking work still remains to be done in this important field.

As steps in advance it may be noted that one of the new sections in the Revised Sanitary Code, which went into effect in New York City with the beginning of this year, requires the reporting of occupational diseases and injuries, and that the Department of Health has recently organized a division of industrial hygiene. The action of the department was the result of a request by Commissioner Goldwater to the Advisory Council that it should consider the advisability of establishing such a new division. The council at once took the matter up, and after due deliberation signified its approval of a measure of this character endorsing the report of a committee of which Dr. George M. Price, of the Joint Board of Sanitary Control, was chairman. In this report it was stated that the general mortality and morbidity of the population are profoundly influenced by the conditions of the industrial establishments in the city, by the hazards of industry, and by health conditions of the industrial population. Private organizations like the Museum of Safety, the Association for Labor Legislation, and the Metropolitan Life Insurance Company are not able, by means of their official functions, to safeguard this industrial population; while the State Labor Department, with its present organization, with its attention necessarily given to the whole state, and with its activities mostly centered upon the safeguarding of machinery and the enforcement of legislation regarding child and woman labor, cannot devote much of its attention to industrial hygiene or to educational propaganda. Investigation and research in regard to occupational diseases, the prevention of industrial poisoning, and the spread of knowledge of industrial hygiene among the industrial population should be legitimate functions for a progressive health department in a great city like New York, in keeping with its general work in the prevention of disease and the preservation of the health of the citizens. It is therefore within the functions of the Department of Health to establish a bureau of industrial hygiene, and the functions of such bureau should be:—

1. The establishment of a central occupational disease clinic for research investigation on the lines of Professor Devoto's clinic for industrial diseases at Milan. Such a clinic should be

separate from the tuberculosis clinics, although acting in harmony with them and in coöperation with the university and hospital clinics throughout the city; it should be the clearing house for all specific occupational diseases and industrial poisonings, should make a study of the prophylaxis of the various industrial affections met with, and should be supplied with ample means for its work of investigation and research.

2. The establishment of an industrial hygiene educational division, which should endeavor by all possible means to spread the knowledge of the causes of industrial poisoning, the preventive measures to be taken in various industries, and right modes of work and living for the industrial population. It should also, in coöperation with the various manufacturers' associations and other existing bodies, as well as with the Department of Education, endeavor to conduct a general campaign of education among employers and workers as to the prevention of occupational diseases and the preservation of the health of the workers.

A bureau of industrial hygiene organized on the lines indicated, the committee urges in concluding, would be a potent factor in the reduction of mortality and morbidity, and would add prestige and credit to the municipality and to its health department.

This new division has been placed under the general supervision of the director of the bureau of infectious diseases, and it is the purpose to have it closely associated with the bureau of public health education. A special clinic for occupational diseases has been opened, and a committee on industrial hygiene of the Advisory Council of the Department of Health has also been organized, the chairman of which is Prof. W. Gilman Thompson, well known as an authority on occupational diseases, who for a number of years has devoted much attention to the subject in the way of general study and especially in connection with the out-patient department of Cornell University Medical College. Among its other members are Charles Baskerville, Ph.D., professor of chemistry in the College of the City of New York; Dr. E. M. Alger, professor of diseases of the eye in the New York Post-Graduate Medical School; Dr. J. B. Andrews, secretary of the American Association for Labor Legislation; Dr. G. M. Price, and other prominent physicians.

FOUR IMPORTANT RECENT LEGAL DECISIONS.

I. LEGAL RESPONSIBILITY FOR POLLUTION OF WATER SUPPLY. An interesting and important decision has recently been rendered by the Supreme Court of New Jersey, relative to legal responsibility for the pollution of water supply. The question arose in conjunction with a suit growing out of an outbreak of typhoid fever in Mount Holly, N. J. The plaintiff, a citizen of that town, sued the local water company for recovery of expenses and indemnification for loss of time due to the illness of his three children during the epidemic. It was shown that the plaintiff had paid the company in advance for a year's water supply covering the period during which the illness occurred. A lower court, before which the suit was first tried, found for the plaintiff, and upon appeal of the defendant this decision was sustained by the supreme court, which found that there was evidence that the water supply was being polluted with sewage and that the company had known of this pollution for upwards of three years before the outbreak of the epidemic. The court held that it was the duty of the water company to supply the plaintiff with pure and wholesome water. This decision was stated by the court as follows:

"Water is a necessity of life and one who undertakes to trade in it and supply customers stands in no different position to those with whom it deals than does a dealer in foodstuffs. He is bound to use reasonable care that whatever is supplied for food or drink shall be ordinarily and reasonably pure and wholesome."

This decision is of importance as establishing a precedent fixing the responsibility of local companies or water boards for pollution of water supply and for illness, damage and loss resulting therefrom.

II. COMPENSATION FOR OCCUPATIONAL DISEASES. In the weekly report of the United States Public Health Service for May 14 is quoted an opinion written by Chief Justice Rugg of the Supreme Judicial Court of Massachusetts construing the workmen's compensation law of this Commonwealth, which provides for compensation for "personal injuries arising out of and because of" the workman's employment. The opinion was rendered in a case in which suit was brought against a life insurance company to recover for the death of one of its beneficiaries.

"The deceased employee was a cook upon a lighter, where his employment required him to

live and be a large part of the time. The craft began to sink and he then made several trips to and from the deck in an attempt to save some clothes and a surveying instrument. With these he hastened to the dock, where he died soon after. He had suffered from valvular disease of the heart, and his exertions in the effort to save his belongings and the excitement incident to the loss of the vessel so aggravated the heart weakness as to cause his death. The perils of the sea were risks arising out of and in the course of the employment of the deceased. The sinking of the boat was obviously one of these perils. It is impossible to say as a matter of law that it is not one of the instincts of our common humanity to try to save from a sinking vessel all of one's possessions that reasonably can be secured. The deceased perhaps exerted himself too much for this purpose, although it would be difficult on the evidence to determine to how great an extent the fatal result was due to that cause rather than to the excitement of the occasion. Under these circumstances the calm and wisdom of quiet and safety can not be expected. Much must be excused to the surrounding commotion. The deceased did not abandon the service of his employer and embark on a venture of his own when he tried to save his clothing. It was an implied term of such service as this that the employee might use reasonable effort to this end in an exigency like that which arose. This is not an instance where the discipline of a ship was violated or a higher duty neglected. It was in the course of his employment to live upon the lighter. Whatever it was reasonable for anyone to do leaving a sinking vessel, which was his temporary home, was within the scope of his employment. The standard to be applied is not that which now, in the light of all that has happened, is seen to have been directly within the line of labor helpful to the master, but that which the ordinary man required to act in such an emergency might do while actuated with a purpose to do his duty."

The Industrial Accident Board found that the death of the employee arose out of and in the course of his employment and the court held that this finding was warranted by the evidence. In its editorial comment upon this case the public health report says:—

"In an opinion which was published in the Public Health Reports, June 12, 1914 (p. 1583), the same court decided that blindness resulting from an acute attack of optic neuritis induced by poisonous gases with which the workman came in contact in his work was a 'personal injury' within the meaning of the law and that the afflicted workman was entitled to compensation.

"Later the court held that lead poisoning was included in the terms of the act. (*Johnson v.*

London Guarantee & Accident Co., Public Health Reports, July 3, 1914, p. 1781.) In the opinion Justice Crosby said: 'It is clear that 'personal injury' under our act includes any injury or disease which arises out of and in the course of the employment which causes incapacity for work and thereby impairs the ability of the employee for earning wages.'

"The decisions above referred to construe the Massachusetts workmen's compensation law as providing for compensation for workmen acquiring acute or chronic disease as a result of occupation, or in the course of employment as well as for workmen injured by industrial accidents."

III. LEGAL STATUS OF CREAM UNDER THE MILK STATUTE. In a recent decision by Judge Carroll of the Supreme Court of Massachusetts, the full bench has for the first time decided that cream is to be subject to the same statute regulations as milk under the terms of the law forbidding adulteration. A local milk company had been found guilty of adding water to the cream which it offered for sale. The company took exception to this decision, defendant claiming that cream and milk are different substances and that the addition of water to cream was not expressly specified in the legal statute. The court overruled this exception, rendering its decision in part as follows:—

"Generally, milk and cream are the same thing, and under the statute seeking to prevent the adulteration of milk by the addition of water or any foreign substance, cream is considered to be the same thing as milk.

"The statute was passed for a purpose. It was to protect the public health. The adulteration may be equally serious, whether it is of the whole milk or in any of its component parts, such as cream or skim milk, and the protection of the consumer is as much desired in the sale of the component parts of milk as in the sale of milk itself."

IV. SUPPRESSION OF A SPURIOUS MEDICAL COLLEGE. On May 21 the full bench of the Massachusetts Supreme Court decided that the New England College of Chiropractic, Inc., has no right to grant the degree of D.C. and upheld the previous decision of the Superior Court which imposed a fine of \$100 for granting this degree without authority. Complaint against this institution was brought on by the fact that a degree signed by seven persons was granted by it in June, 1914. It was declared by the court that this degree was not a degree in the legal sense. In its decision the court said:—

"The word doctor used in connection with an unusual and high sounding word would be quite as likely to impose on the ignorant and credulous as the false use of the conventional Doctor of Medicine.

"The conferring of a title made up of the word doctor and a word relating to the healing art may be found to be the granting of a degree in the meaning of the statute.

"When a title like doctor, commonly associated with unusual skill acquired by academic or professional study, is conferred without right, the statute is violated.

"The ordinary diploma of public or private schools does not contravene the statute, but simply certifies to the completion of a course of study."

This decision is of importance as a precedent in the suppression of illegal and spurious medical colleges.

THE MILK SUPPLY AND BOVINE TUBERCULOSIS

As the sources of the milk supply become varied and separated to keep pace with the demand so does the problem of obtaining a pure and disease-free supply become a more difficult one to solve. As a food milk is the largest single element, and in children it is largely the sole food element. To this end the larger centres of population have made various sanitary regulations with regard to the care and condition of the cows and the handling of the milk, to which dairies must conform as a condition precedent to being allowed to contribute to the milk supply of that centre—and the courts have upheld even the most stringent regulations in this respect as constitutional. Some of the milk concerns of their own volition have even improved on these regulations, and in order to insure their supply from contamination from contagious disease present on the dairy grounds they accept but throw away all milk produced during the period of contagion, so that there will be no excuse for withholding the fact of the disease from the concerns.

In the class of the stringent regulations can be placed the tuberculin tests. The test is applied to cows before their admission to the herd and repeated about every six months. Naturally, opposition to a measure which renders valueless so large a number of cattle has been very severe. And the separation of so many cattle from con-

tributing to the milk supply has decreased that supply and greatly increased the cost to the consumers. But the large number of tuberculous cattle discovered by these tests fully justifies the measure. In some instances whole herds were found affected.

On the other hand there has been a tendency to minimize and even to disclaim any danger to man from the bovine type of tuberculosis. At one time even Koch maintained that the bovine type of tuberculosis was not pathological for man. Later he admitted that there was slight pathogenesis for man. The morphological differences between the two types though slight are yet positive. The human type grows more luxuriantly on the usual culture media than the bovine type. The bovine tubercle bacillus is shorter, plumper and stains more uniformly. The human type is preponderatingly pathological for man while the bovine type is pathological for nearly all animals but comparatively little for man. Of all forms of tuberculosis in man it is estimated that about 7% are of bovine origin. This percentage is large when it is remembered that pulmonary tuberculosis, which is such a large item in human tuberculosis, is never found associated with the bovine bacillus. The bovine type is commonly associated with tuberculosis of the lymph glands of the neck and abdomen. About 60% of this form of tuberculosis is bovine. The contention that gland tuberculosis immunizes against other forms of tuberculosis has no proof and does not make this form of tuberculosis desirable. Furthermore, from one half to one fourth of all tuberculosis in children is bovine—and, therefore, ingestion tuberculosis. Meningeal and generalized tuberculosis in children is over 65% bovine. Roughly, the bovine morbidity for persons over 16 is 1.5%; between 5 and 16 years it is 25%, and under 5 years it is 50%. It can be seen that the percentage decreases as milk ceases to be the predominating food element.

The portal of entry for the bovine tubercle bacillus is through the tonsils and the small intestines. The bacillus is derived from tuberculosis of the udder and ingested by human beings. There is comparatively little danger from meat directly because tuberculosis of the muscles is rare and because meat is usually cooked before consumption. Meat may, however, become infected from neighboring organs because of the careless butchering.

When a large number of tubercular infections in man are traced to bovine tuberculosis the necessity for controlling the bovine menace becomes forceful. The effect on the morbidity and the mortality generally, but especially in children who are so largely forced to subsist on milk, will more than repay the cost of producing tuberculosis-free milk. Every case of bovine tuberculosis in man is an ingestion tuberculosis and therefore preventable. The campaign against tuberculosis in man becomes nugatory unless it includes a campaign against tuberculosis in cattle. Proper sanitary methods, sufficient floor and air space and suitable food will prevent tuberculosis in them as in man. Bovine tuberculosis is as much a factor in human tuberculosis as improperly cared for human tuberculosis is a factor in the spread of human tuberculosis. These two factors eliminated the millennium in tuberculosis is accomplished.

BOSTON CONFERENCE ON ILLEGITIMACY.

THE work hitherto accomplished of the Boston Conference on Illegitimacy has appeared in a modest pamphlet privately printed of forty-eight pages. The conference is made up of a group of workers who aim to deal personally with unmarried mothers and who have joined forces in order more clearly to define the problem concerning these women. Two methods have been adopted to accomplish this end. First what might be called a case system plan of discussion of actual cases and secondly, through the formation of groups of workers for special study. Six of these latter groups have undertaken to investigate such subjects as legislation, feeble-mindedness, syphilis, the problem of utilizing facts in the possession of various societies and hospitals, the problem of handicaps other than mental defects leading to illegitimacy and finally the problem of appraising the stigma ordinarily attached to such delinquency.

As might well be expected it is again evident from a reading of the pamphlet that the problem of illegitimacy is one of the most difficult which social workers are called upon to study and it is, therefore, not at all surprising to find that no definite results have, as yet, been attained. As the president, Mrs. A. E. Sheffield,

states, "the positive achievement of the conference at the present stage of its work, lies not so much in conclusions upon the matters of its study, as in contributing something in a peculiarly intricate field toward a sound, critical method." This is certainly no mean achievement and there can be no doubt that it has in large measure been accomplished by the extraordinarily objective and painstaking work of the various members of the conference often under conditions of extreme difficulty. The questions involved are naturally as old as civilization and become increasingly difficult of solution under the various complexities of our modern life and industrial conditions. The intricacy of the matter, however, should be a stimulus rather than a deterrent in getting at all the facts available. When such facts are accumulated there should be more reasonable basis for legislation and for the direction of the public opinion than can possibly exist in the present chaotic state of knowledge on the subject. The problem, however, must go far beyond social conditions. It is evident that standards vary widely in different countries and no doubt in different sections of the same country. That such matters of personal morality can ever be determined or controlled by legislative enactment is not to be seriously considered. The present situation in the countries of Europe may be taken as an example in a broad way, of some of the difficulties in arriving at a universal standard. All this, however, in no way militates against just the sort of work this Boston conference is attempting to do. So long as it remains objective and seeks primarily to discover and appraise facts its efforts should be most earnestly encouraged. If, however, the temptation to theorize and draw hasty deductions should creep in we feel that a large part of its usefulness would be lost. We are therefore extremely glad to note that in this first report no effort whatever is made to draw conclusions except in the most general possible way. The recommendations made are moderate and eminently sane. They should certainly receive careful attention.

THE MASSACHUSETTS STATE BOARD OF INSANITY announces an exhibit of hand-work by patients in institutions under this board, at the State House, Boston, from 10 a.m. to 4 p.m., June 7-15, 1915, inclusive. All who are interested in the welfare of the mentally ill and in occupational therapy are cordially invited. The State House closes at 12 m. on Saturdays.

COMPLIMENTARY DINNER TO DR. THEOBALD SMITH.

The postponed complimentary subscription dinner to Dr. Theobald Smith, George Fabyan professor of comparative pathology in the Harvard Medical School, was held at the Harvard Club on Wednesday evening, June 2, and was attended by about 200 of Dr. Smith's professional colleagues and friends. The occasion was planned as a testimonial of respect, appreciation and good wishes to Dr. Smith upon his completion of more than twenty years of service to the School and to the State, from which he now withdraws to undertake even larger duties as director of the new school of research in animal diseases, recently established in New Jersey by the Rockefeller Institute for Medical Research.

President Abbott Lawrence Lowell acted as toastmaster and introduced successively the speakers of the evening, who were Dr. Frederick C. Shattuck of Boston, Dr. William S. Thayer of Baltimore, Dr. Simon Flexner of New York, Dr. Charles W. Eliot of Cambridge, Dr. William H. Welch of Baltimore, and Dr. Edward H. Bradford of Boston. President Lowell then read extracts from a number of letters received from men of science throughout the world, expressing their admiration and respect for Dr. Smith and the work which he has accomplished. Dr. Smith, in a brief closing address spoke with characteristic modesty of the circumstances attending his long period of service to the Medical School, emphasizing the fact that during this time the University, by standing behind the antitoxin, vaccine and other products of the Bussey Institute laboratory, has rendered to the state and community a service of the utmost value and importance.

As a tribute of esteem to Dr. Smith and an expression of the good wishes of the profession to him in his new labors, the dinner proved an even greater success than could be anticipated. The credit for its successful organization and administration belongs to the energy and fidelity of Dr. Marshal Fabyan and his coadjutors. It is expected that a fuller account of the dinner and of the addresses will be published in a subsequent issue of the JOURNAL.

MEDICAL NOTES.

THE MAYO FOUNDATION FOR MEDICAL RESEARCH.—In the JOURNAL of February 18, 1915,

notice was made of the \$1,000,000 endowment fund given by the Drs. Mayo of Rochester, Minn., for the establishment of a foundation for medical research in affiliation with the University of Minnesota. Later, in the JOURNAL of May 6, 1915, mention was made of the bill passed by the Minnesota Senate prohibiting this affiliation. It is now reported that arrangements are being completed which will be satisfactory to both the University and the Mayo Foundation, whereby the University of Minnesota comes into absolute possession of a fund of \$1,500,000, the only condition being that part of the work shall be done in Rochester. The regents of the University will have sole charge of the teaching staff, salaries and general administration, the Mayo Foundation paying all expenses and allowing the \$1,500,000 fund to accumulate, which, when it is finally turned over to the University will, it is expected, have increased to \$2,000,000.

The Mayo Foundation of the University of Minnesota, as it will be called, will be ready to be put in operation when the University opens in September.

NEW YORK HEALTH DEPARTMENT REPORTS LOW DEATH RATE.—There were 1449 deaths and a rate of 13.02 reported during the past week as against 1547 deaths and a rate of 14.46 during the corresponding week in 1914, a decrease of 98 in the absolute figures and a rate of 1.44 points, which is equivalent to a decrease in the relative figures of 160 deaths.

Scarlet fever, typhoid fever, diphtheria and croup, diarrheal diseases, organic heart diseases, acute bronchitis, lobar pneumonia, pulmonary tuberculosis, diseases of the nervous system, and deaths from violence all showed considerably decreased mortalities.

There were only a few causes which showed an increased mortality, among them measles and whooping-cough, but the increase in each instance was exceedingly small.

Viewed from the point of age grouping, there was no one age group which showed an increased mortality, infants under one year and between one and five years showed a decreased mortality of 3%, the greatest saving of lives having been among the young adults, the decreased mortality over 65 years of age being small in comparison.

The death rate for the first 22 weeks of 1915 was 14.51 per one thousand of the population as compared with the rate of 15.29 in the corresponding period of 1914, a decrease of .78 of a point.

GIFT TO CINCINNATI MEDICAL COLLEGE.—Report from Cincinnati on May 25 announces a gift of \$250,000 from Mrs. Mary Emery of that city to the Cincinnati Hospital. A similar amount is to be raised by the hospital commission and the whole will be applied to the erection and equipment of a new medical school to be located near the hospital and administered in

conjunction with it by the Ohio-Miami Medical College.

PREVALENCE OF MENINGITIS, POLIOMYELITIS AND TYPHOID.—The weekly report of the United States Public Health Service for May 21, 1915, states that during the month of April, 15 cases of cerebro-spinal meningitis were reported from Massachusetts and 10 from Wisconsin. During the same month there were six cases of poliomyelitis each in Maryland and Massachusetts; and of typhoid fever there were 55 cases in Maryland, 64 in Massachusetts, 21 in Vermont and 33 in Wisconsin.

RECIPIENTS OF HONORARY DEGREES.—At the inauguration of Dr. Frank J. Goodnow as president of Johns Hopkins University degrees were conferred on twelve distinguished scholars and scientific men, among them being Dr. Simon Flexner, director of the laboratories of the Rockefeller Institute for Medical Research, and Dr. Thomas Hunt Morgan, professor of experimental zoology, Columbia University.

BERI-BERI ABOARD A BRITISH STEAMER.—Report from New York on May 26 states that 25 cases of beri-beri have been reported as occurring on the British steamer *Deva*, which sailed from Havana May 4 for Cienfuegos, and is now on her way to New York. Eight of the crew of 40 men have died since the vessel sailed.

MILITIA MEDICAL SCHOOL IN TEXAS.—Report from San Antonio, Texas, states that on May 26 a new school in army medical practice for the officers of the state militia of Texas, Arkansas, Oklahoma and Louisiana was opened at Fort Sam Houston. The camp is completely equipped with a field hospital, ambulance corps and regimental infirmary and the classes are to be taught by army officers of the medical department.

GIFT FOR RESEARCH IN SOCIAL HYGIENE.—Dr. Winford H. Smith, superintendent of the Johns Hopkins Hospital in Baltimore, has recently announced a gift from Mr. John D. Rockefeller, Jr., of \$16,500 to be used for the maintenance of the social hygiene department which is to be established at the hospital in September. Dr. Albert Keiden, with four assistants, will be in charge of the work.

NATIONAL CONFERENCE OF TUBERCULOSIS SECRETARIES.—There will be held at Seattle, Wash., June 15 and 16, 1915, the third annual meeting of the National Conference of Tuberculosis Secretaries and the eleventh annual meeting of the Sociological Section of the National Association for the Study and Prevention of Tuberculosis.

In the morning of June 15 the latter organization will hold a symposium on "The Official Responsibility of the State and Its Civil Subdivisions." Dr. William C. White will discuss "The State," Dr. Theodore B. Sachs, "The City" and Dr. George J. Nelbach, "The Country."

This will be followed by a symposium on "The Duties and Opportunities of the Private Associations," with addresses by Miss Edythe L. M. Tate on "The State Association," James Minnick on "The Local Association" and Dr. Charles J. Hatfield on "The Relations the State and Local Associations Should Sustain to Each Other." On the following day there will be a symposium on "Housing in Relation to Tuberculosis," with addresses by Dr. Isaac W. Brewer on "House Infection—A Very Potent Source of Tuberculosis," Dr. Charles J. Hastings on "Relative Prevalence of Tuberculosis Under Good and Bad Housing Conditions" and by Lawrence Veiller on "A Legislative Program." The Conference of Tuberculosis Secretaries will hold a symposium on the 15th on "Programs of Anti-Tuberculosis Work," with addresses by Walter D. Thurber entitled "For the Cities," Dixon Van Blarcom, "For the Counties and Rural Districts" and Charles M. DeForest on "Red Cross Seals; How to Sell Them."

DECLINE OF PARISIAN BIRTH RATE.—Report from Paris on June 1 indicates that the European War is already beginning to show its effect on the declining French birth rate. During the month of May there were only 1850 births in Paris as compared with 3890 during the same month in 1914.

GERMAN SURGICAL ASSOCIATION.—The regular annual meeting of the German Surgical Association was held at Brussels from April 7 to 10 inclusive, and was attended by several hundred members. All the sessions were devoted to military surgery. The principal addresses were delivered by Drs. Garré, Körte, Payr and Bier.

EUROPEAN WAR NOTES.—Reports received by the United States Public Health Service show that from August 1 to December 31, 1914, there were in Austria 279 cases of typhus fever. Between January 1 and March 20, 3466 cases were reported, and from March 20 to April 3, 439 cases were reported in nine provinces alone. In Vienna there were 16 cases during the week ended April 10.

It is announced that the Harvard Dental School will soon send to Europe ten dental surgeons for service in the dental department of the French base hospital at Paris. It is intended that these experts shall take charge particularly of the treatment of gunshot fractures of the jaw and other injuries about the face involving a knowledge of oral surgery.

Fifteen women nurses from the French Hospital in New York sailed, on May 30, for Bordeaux, where they will join the French Red Cross.

It is announced that during June the University of Pennsylvania will send to the American Ambulance Hospital at Neuilly, Paris, a surgical unit to take charge of the American University ward in that institution during July, Aug-

ust and September. The personnel of this unit will consist of Dr. J. William White, Dr. James P. Hutchinson; neurologist, Dr. Samuel J. McCarthy; assistant surgeons, Dr. Edmund P. Piper, Dr. Walter S. Lee, Dr. Arthur G. Billings and Dr. Peter McC. Keating; bacteriologist, Dr. Samuel Goldschmidt Girvin, fellow in research medicine, University of Pennsylvania; nurses, Mrs. M. E. Spry, long chief clinic nurse of University Hospital; Miss Jackson and Miss Wagner; anesthetist, Miss Frazer. It is expected that Johns Hopkins University will send an expedition to take charge of this ward during October, November and December and the University of Chicago in January, February and March, 1916.

It is announced by the Serbian agricultural relief committee that it has recently sent to Dr. Richard P. Strong of the American Red Cross Sanitary Commission at Nish, Serbia, a shipment of materials valued at \$37,392.75. "It includes 125 tons of sulphur, 5000 gallons of kerosene, 2500 gallons of phinotas oil, 9800 pounds of paste flour, 750 iron pans, 500 Dutch ovens, one box of automobile tools, 10 sterilizers, 500,000 bichloride tablets, five tons of paper, 50 tons of plunge tubs, 80 packages of tents, 2700 cakes of soap, five barrels of alcohol, 500 gallons of formaldehyde, 100 gallons of pure alcohol, two cases of acetic acid, mercurial ointment and permanganate of potash, three cases of cholera vaccine and 596 packages of artesian well supplies.

"In addition, 43 cases of hospital garments, 83 cases of hospital supplies and 32 cases of clothing were sent to the Serbian Red Cross at Nish. Twelve cases of hospital supplies went to Dr. E. W. Ryan of the American Red Cross unit at Belgrade, one case of hospital garments and eight cases of supplies to Dr. Ethan Flagg Butler, at Geveglia and one case of cots to the Sanitary Commission."

On June 6 the totals of the principal New England relief funds for the European war reached the following amounts:—

Belgian Fund	\$260,874.08
Red Cross Fund	134,933.65
Jewish Fund	62,774.20
Polish Fund	46,668.59
Serbian Fund	31,842.25
British Imperial Fund	29,872.28
Belgian Red Cross Fund	13,721.00

The principal amounts contributed by various states to the St. George's Fund are as follows:—

Massachusetts	\$9,860.19
Pennsylvania	4,830.41
New Jersey	4,032.00
Connecticut	3,800.00
New York	3,173.57
Illinois	3,139.89
Pacific Coast	2,146.92
Michigan	1,785.95
Ohio	1,286.87
Rhode Island	1,200.45

BOSTON AND NEW ENGLAND.

MEASLES EPIDEMIC IN MILTON. An epidemic of measles is reported among school children in Milton, Mass. On May 29, 188 cases had occurred. No clue as to the source of the epidemic has been given.

MOUNT SINAI HOSPITAL.—The thirteenth annual report of the Mount Sinai Hospital records the work of that institution for the year 1914. The total treatments numbered 27,680, of which 6,039 were given free. There has been opened during the year a genito-urinary clinic. It is conducted on two evenings a week and has an average attendance of 28. A clinic for speech defects was organized in March, 1914, and has treated 14 patients, three of whom have been discharged as cured. The hospital is sorely in need of a new building. Its present quarters are wholly inadequate to take care of the patients who apply for treatment and every effort is being urged to make the erection of a much larger building possible.

BOSTON MILK AND BABY HYGIENE ASSOCIATION.—The Boston Milk and Baby Hygiene Association has recently issued an urgent appeal for funds for carrying on its regular work during the current season. The financial complications associated with the European War make the difficulty of paying the necessary amounts even greater than usual, and especial generosity is needed since the work of the Association is likely to be larger this year than ever before.

"Already the Association is caring for 24% more babies than ever before at this season, and the numbers are bound to increase. For the first four months of 1914, the infant mortality was brought down so that baby deaths were 72 fewer than in the same period of the previous year; but in the same period during the current year it was possible to diminish the deaths of babies under one year by only 11, as compared with last year. Conditions are even worse in New York, ascribed also to the lack of employment and proper nourishment, the infant deaths having actually increased in the first quarter this year to 3399, as against 3372 for the same period in 1914. In New York additional clean milk stations have been opened already to meet the increased need.

"The method which the Milk and Baby Hygiene Association feels to be effective, as well as by far the most economical, is to add nurses for temporary work from June to October in the milk stations where more babies are now registered than the regular nurse can properly supervise. Special funds are needed for four such "summer nurses" for the North End, the West End, East Boston and South Boston. Additional "well baby clinics" must be opened in several of the stations."

THE CRUISE OF THE ANDROS-COGGIN.—In the issue of the JOURNAL for February 4, we com-

mented editorially on the first six weeks' cruise of the revenue cutter *Androscoggin*, as a hospital ship for deep sea fisheries off the New England and Newfoundland coast. Since that time the *Androscoggin* has continued its highly efficient and successful work in this service and has recently returned to the Charlestown Navy Yard from a thirty-eight day cruise along the Provinces, during which she picked up three fishermen off the Sable Islands and two Canadians who were treated by the ship's surgeon. During the past five months the *Androscoggin* has cruised over 9,000 miles in the hospital service and has treated over 100 cases among fishermen, seven of whom were picked up at sea, the others being taken aboard at port stations.

HOSPITAL BEQUESTS.—The will of the late Charles W. Emerson of Newton, Mass., who died on April 4, has recently been offered for probate. It contains reversionary bequests of \$15,000 to the Newton Hospital and \$10,000 to the New England Peabody Home for Crippled Children.

PASSAGE OF THE DENTAL REGISTRATION BILL.—In the issue of the *JOURNAL* for April 15, we again commented editorially on the Dental Registration Bill then pending before the Massachusetts General Court. This bill has since been passed by the legislature and on May 28 was signed by Governor Walsh. The passage of this bill, which has been consistently advocated by the *JOURNAL*, was opposed chiefly by the present State Board of Registration in Dentistry on account of the so-called dental nurse clause. In the bill as finally passed this clause was so drawn as to eliminate the dental nurse from private practice and limit her work to the maintenance of oral hygiene in public institutions.

TRANSFER OF BOSTON QUARANTINE STATION.—On June 1 the transfer of the Boston Quarantine Station from local to federal control became effective and the administration of the station was assumed by Dr. Samuel Bates Grubs of the United States Public Health Service, who has been detailed for this duty. All the city employees in the quarantine service are taken over by the government and now become federal officials. The Boston Quarantine Station was established on Gallop's Island in 1860 and since the organization of the Boston Board of Health in 1872, has been under the administration of that body. The first hospital was erected on the island in 1873, and dormitories were built in 1892. During the year 1913, 795 vessels were inspected at quarantine and 174 cases of various diseases were treated at the station.

DECLINATION OF DR. CREEL AS HEALTH COMMISSIONER.—In the issue of the *JOURNAL* for May 13, we announced the acceptance by Dr. Richard H. Creel of the United States Public Health Service of an appointment as Health Commissioner

of the city of Boston. It is now announced that Dr. Creel has unfortunately found it necessary on account of his health, to reconsider this acceptance. His letter of refusal, stating his reasons for this action is in part as follows:—

"It is with much regret that I feel constrained to reconsider my tentative acceptance of your tender of the position as Commissioner of Health of Boston. The changed conditions which influence me to this decision are largely personal and chiefly a question of my physical condition. I have spent several long and trying details in the tropics, with various attacks of malaria always under adverse conditions.

"During this past month, subsequent to the onset of warm weather, I have again experienced the return of ill health. At the present I feel that I would not be able to assume charge of the work with a keen enthusiasm which would be so essential to success.

"I would feel a moral obligation to go forward with the work did I not realize that there are other men in this service and out of it that are available for the vacant position, men who will be only too eager to accept a post that carries with it such possibilities for professional advancement and honor. With such other available candidates, it would seem ill advised for one not up to the full standard of efficiency to attempt the position."

This declination on Dr. Creel's part is sincerely to be regretted and it is earnestly to be hoped that an equally judicious and satisfactory selection may be made of the next candidate to whom this important position may be offered.

HARVARD MEDICAL ALUMNI ASSOCIATION: TRIENNIAL MEETING, MAY 20, 1915.—A very successful and enjoyable meeting of the Harvard Medical Alumni Association was held on May 20th. In the morning the Massachusetts General Hospital, the Boston City Hospital, the Free Hospital for Women, and the Boston Psychopathic Hospital gave demonstrations in many of the departments with ward visits and special clinics in the operating rooms. These were much appreciated by a large number of men who showed a keen interest in the newer methods which were demonstrated.

A luncheon was served in the Museum of the Administration Building of the Harvard Medical School. About 180 men attended this luncheon which was furnished by members of the Harvard Medical School Faculty. The beautiful room with its valuable collections added much to the pleasure of the occasion.

In the afternoon the nearby hospitals, the Peter Bent Brigham, the Children's, and the Cancer Hospitals were visited. All the departments of the Medical School were open for inspection to the alumni while the classes were in session. Certain of the departments, such as the Physiological Department and the Department of Hygiene and Preventive Medicine, prepared

special demonstrations and gave short talks on the work which each man in the department was doing at the time. Considerable interest was shown in the new ideas which were being tested out, and many questions were asked. In the amphitheatre of Building D, three demonstrations were given with lantern slides.

In the evening the Triennial Dinner was served in the large room at the Harvard Club. Two hundred and twenty men were present. Dr. S. B. Woodward, President of the H. M. A. A., presided and introduced the speakers who were Dr. H. P. Walcott, member of the Corporation of Harvard University, Dr. E. H. Bradford, Dean of the Medical School, Dr. H. D. Arnold, Dean of the Graduate School of Medicine, Dr. Haven Emerson, Deputy Commissioner of Health of New York, Dr. F. W. Peabody, member of the China Medical Board, and Dr. Harvey Cushing, who has lately returned from the war in France and England.

The Triennial Meeting proved instructive and enjoyable and gave those who attended a chance to get in touch with the School in working hours, to have a glimpse of the new work that is going on, and to renew old acquaintances of Medical School days.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending June 1, 1915: Diphtheria 76, of which 8 were non-resident; scarlatina 117, of which 9 were non-resident; typhoid fever 4; measles 221, of which 3 were non-resident; tuberculosis 75, of which 1 was non-resident. The death rate of the reported deaths for the week was 15.86.

Obituary

SIR WILLIAM RICHARD GOWERS, M.D.
F.R.C.P., F.R.S.

DR. WILLIAM RICHARD GOWERS, who died on May 4 at London, was born in that city on March 20, 1845. He was early entered at Christ Church, Oxford, and, graduating from that college in his seventeenth year, was immediately apprenticed to a country surgeon at Coggeshall, Essex. Subsequently he pursued his medical education at University College and Hospital, London, receiving the degree of M.R.C.S. in 1867, that of M.B. in 1869, and that of M.D., with a gold medal in 1870. He was immediately appointed medical registrar to the National Hospital for the Paralyzed and Epileptic. During his student days he had served as private secretary to Sir William Jenner and continued in this capacity for many years thereafter. "The daily intercourse with that intellect," says Gowers, "was a privilege inestimable"; and apparently the influence of Jenner had a very marked effect in determining the career of his brilliant young assistant.

In 1873 Gowers was promoted to be assistant physician to the Hospital for Paralyzed and Epileptic, where he finally became full physician in 1880. He had already been appointed assistant physician to University College Hospital in 1872 and became physician there in 1883. Upon his retirement from the staff in 1888 he was appointed consulting physician. He also served for many years as assistant in clinical medicine at the University College Medical School and at a later date for several years, held a professorship in this subject. He became a member of the Royal College of Physicians of London in 1875 and a Fellow in 1879. In 1880 he delivered the Goulstonian lecture on "Epilepsy and Other Chronic Disorders," and in 1890 the Bradshaw lecture on "Subjective Sensations of Sound." He was elected a Fellow of the Royal Society in 1887.

From the very outset of his medical career Dr. Gowers was especially interested in diseases of the nervous system. As early as 1876 he edited the sections on the brain and spinal cord in the eighth edition of Quain's *Anatomy*. His earliest papers in the *British Medical Journal* were on chorea and the diagnosis and treatment of auditory vertigo. In 1876 also he published his first book, an essay on athetosis and post-hemiplegic disorders of movement, beautifully illustrated by drawings of his own. In 1877 he invented a hemoglobinometer, which was used in England until its replacement by the Thoma-Zeiss instrument. The solution which he employed, however, for blood corpuscle estimation, is still widely in use. In 1879 he published an important work on medical ophthalmology, in which he continued the work of Hughlings Jackson in emphasizing and elaborating the importance of the ophthalmoscope in neurology. The illustrations in this book also were all drawn by Gowers himself. In the same year he published another small book on pseudohypertrophic muscular paralysis.

In 1880 appeared what is, perhaps, Gowers' most famous work on "The Diagnosis of Diseases of the Spinal Cord," which went through many subsequent editions. It was in this work that he first referred to and illustrated the thirto unrecognized tract of fibres in the gray matter which he himself called the antero-lateral ascending tract, but which ever since has been known by his name. He discovered this tract while examining the spinal cord of a case in which the lower end of the cord had been crushed by a fracture of the spine, and described "a symmetrical area of slight ascending degeneration in the anterior part of the lateral columns in front of the pyramidal tracts." He believed the function of the fibres in this tract to be conductive of sensation.

During the years which followed, Gowers continued to combine his active professional life in hospital and private practice with further researches in neurological subjects and the story

of the later part of his life is essentially the chronology of his publications. In 1881 appeared his book on epilepsy, based on 1450 cases of his personal observation. The second edition of this work, published in 1901, contained the record of 3000 cases. In 1886 appeared his "Manual of Diseases of the Nervous System" in two volumes, which went through several editions and was later translated into German and Italian. In 1890 he delivered the Lettsomian Lectures before the London Medical Society, and on these based, in 1892, his work on "Syphilis and the Nervous System." One of his latest works was "The Borderland of Epilepsy," published in 1907.

As a result of his prolific and brilliant professional activities, Dr. Gowers soon acquired an international reputation and was made an honorary member of many foreign medical societies, including the American Neurological Association. He received the honor of knighthood in June, 1897, at the diamond jubilee of Queen Victoria.

He survived by two daughters and two sons.

LIEUT.-COL. CHARLES DALTON, M.D.

DR. CHARLES DALTON, an Irish army medical surgeon, who was wounded at Verneuil, France, died at Vieil Arcy on September 18, 1914. In the January issue of the *Journal of the Royal Army Medical Corps* is published a sketch of his adventurous and gallant career.

Charles Dalton was educated at Trinity College, Dublin, and qualified as a practitioner in 1888. He immediately shipped as surgeon aboard the Royal Mail Steamer *Cotopaxi*, and within a year was wrecked in that vessel when she struck a reef in the Straits of Magellan, foundering in eight minutes. Among the passengers aboard were two men who were paralyzed. Dalton carried them both to safety in a boat and rendered service of conspicuous gallantry in the rescue of the remaining two hundred passengers, not one of whom was lost. The French Government recognized this service by awarding him a medal of honor of the first class.

In 1891, Dalton joined the Royal Army Medical Corps and in 1897, while serving in the Northwest Indian Frontier expedition, saved the lives of a number of his men who were suffering from insolation by applying the constant immersion treatment in a stream of cool running water. In 1898, while serving in Sierra Leone, he was twice mentioned in dispatches for gallant conduct under fire. On one of these occasions he rescued a dangerously wounded lieutenant from within a few yards of the enemy's stockade under an extremely heavy fire.

Dr. Dalton served throughout the Boer War in South Africa and there, while attending a wounded comrade under fire, was shot through

the stomach and remained lying on the battlefield for 12 hours. He then dragged himself to the British camp, directed the sending of ambulances to remove other wounded men from the field and allowed himself to be operated upon only after all the others had been attended to. After surviving this experience, he returned to Ireland, where, in the succeeding years of peace, he became a busy country practitioner. He also indulged extensively in his favorite sport of steeple chase riding in which he was a noted and daring figure.

At the outbreak of the present European War, Dr. Dalton volunteered his services, and was sent out with the first expeditionary force as lieutenant-colonel in charge of general hospital No. 1. At the battle of Verneuil while carrying in wounded under fire from the field of action, he was struck by a shell and while lying on the ground was run over by a stampeding gun limber which crushed his left thigh. The wound became infected and he died on September 18. So brilliant and romantic a career seldom falls to the lot of the surgeon in military service, but the fearlessness and devotion shown in every emergency by Dr. Dalton, are examples of bravery often shown and seldom recorded.

Miscellany.

THE CALIFORNIA CLIMATE AND THE TREATMENT OF TUBERCULOSIS.

In the recently published February bulletin of the Medico-Chirurgical College of Philadelphia appeared an article on "The Climate of California," representing a lecture delivered by Dr. Guy Hinsdale of Hot Springs, Va., in the course on pharmacology at the college this year. This article presents an interesting study of the California climate with special relation to its adaptability to the treatment of pulmonary tuberculosis. There is presented also a diagram illustrating the average precipitation in inches, and its seasonal distribution at Los Angeles and at Mt. Lowe, during the periods from 1896 to 1902 and from 1904 to 1913. In conclusion Dr. Hinsdale quotes from an article of Dr. H. F. Ziegel (*N. Y. Med. Jour.*, Dec. 15, 1906) the following summary of the various climates of Southern California.

"1. The Mountain Climate.—Four thousand feet and upwards. Idyllwild, in Riverside County, is a good example. It is on the slopes of the San Jacinto mountain, at an elevation of 5200 feet in the Strawberry Valley. It is a mountain park twenty miles from a railway and abounding in pines, with a sandy soil, delightful, stimulating air, a substantial snowfall in winter and with all the characteristics of highest

oints of the Adirondaeks, except the absence of lakes and cloudy weather. Four thousand to 6000 feet of elevation may render any place more or less detrimental to the aged or those with any disease of the circulatory organs. For any cases of nervous disease it is excellent.

"2. The Foothill Climate.—Of the various climates met with in Southern California this possesses the most advantages with the fewest disadvantages. As a result of the moderate altitude—1500 to 3000 feet—there are less fog, less humidity, and fewer cloudy days than near the coast, the nearby mountains afford shelter from the wind currents, and consequently the diurnal ranges of temperature are reduced to a minimum. But any good climate depends upon something more than altitude—wind currents, rainfall, sunlight, humidity, proximity to the sea and mountains, etc. Of the formidable list of thirty-six climatic factors which Dr. Hann says ought to be embodied in a full discussion of the climatology of any locality, among the most important is geological formation. It is a common experience to have observed marked differences in places close together in which all those factors except the last mentioned are the same. In one place, if one sits outside late in the afternoon of summer's day, one notices the dampness and begins to feel chilled; in another place not many miles away, one can camp out at night without any ill effects. The secret of the difference lies in the character of the soil; the former place probably has a deep, slaty subsoil, while the latter is probably rocky with a sandy covering. Great upheavals, that once upon a time took place in the mountainous districts, have resulted in geological formations contributing largely to the fine foothill climate, which possesses the combined advantages of dry soil, dry air, and moderate elevation without the disadvantages of greater altitudes or the coast districts.

"3. The Desert Climate.—While possessing the advantages of dryness and equability, the desert regions of Southern California are, nevertheless unsuitable for climatotherapy, for they are very hot, and the dry winds are laden with alkaline dust, which is very irritating to the mucous membranes. Moreover, the desert lacks the conveniences of civilization. To obtain the combination of low altitude, considerable sunshine, dryness, as well as purity of the air and equability, it is necessary to go to New Mexico or Arizona.

"4. The Coast Climate.—This we dismiss with a word, having already seen that the humidity, fogs, and extremes of temperatures are serious objections to the marine climate.

"5. The Insular Climate.—The only one of the Channel Islands inhabited to any extent is Santa Catalina, which is about twenty miles west of the mainland. The sea air and considerable humidity are not an objection; this insular climate is amongst the best of all. Ninety-five per cent. of the days are sunshiny; the fog, so

frequent along the coast of the mainland, is seldom seen here, and the temperature is much more equable."

In this connection there is associated interest in another article by Dr. Hinsdale appearing in the issue of *The Child* for April, 1915, on "Open Air Recreation and Instruction," with especial reference to open air theatres, schools, hospitals and sanatoria in the control and treatment of tuberculosis in children. The author refers particularly to the work of the American Open Air School Association, which was organized on April 25, 1914, and since that time has studied actively the problems connected with the education of tuberculous children.

It is a society of practical open-air school workers in the United States, formed for the purpose of (a) coöperative study of the benefits of open-air schools and open-window classes established in various cities in America; (b) encouraging the establishment of similar fresh-air schools in other communities by gathering statistics and preparing reports for school boards and bulletins for the educational and medical press, newspapers and magazines; (c) the dissemination of knowledge concerning the causes of physical subnormality in children, and (d) the scientific study of ventilation and fresh-air supply of schoolhouses and schoolrooms. There are 136 members. An illustrated bulletin is published. The meeting held at Philadelphia, Sept. 22 to 29, was in conjunction with the Fourth International Congress on Home Education. Dr. W. W. Roach, of Philadelphia, is the secretary.

MEDICAL CONTRIBUTIONS BY GERMAN MILITARY SURGEONS.

A CORRESPONDENT in a recent issue of the *British Medical Journal* presents a report of recent medical contributions by German military surgeons based on experiences in the present war, the following extracts from which seem of interest:—

"Professor Goldscheider, a physician with the army, reports on the vaccine treatment of typhoid, having been induced to try it by the experience of a prophylactic dose which happened to fall in the prodromal period. The Marx vaccine was used in a dose of 250-750 million bacilli. Fifty-seven cases were so treated, and in 55 out of 70 injections a remission of fever followed on the first to third day, lasting an average of two days, and sometimes coinciding with the final defervescence. In the remaining cases there was an increase of fever, but not of a serious character. Otherwise no special effect on symptoms was observed, the local reaction being less than in the healthy subject. Nor was any influence of a previous prophylactic inoculation to be observed. Unfortunately in the more severe cases

of disease only the smaller doses of vaccine could be employed. Dr. M. Rhein records a smaller series of cases at Strassburg, using the Halle vaccine diluted 1 in 20, a dose of 0.6 to 1.4 c.c. into the ulnar vein. In 94% of patients a rise of temperature with rigor followed in from half an hour to 2½ hours with subsequent rapid defervescence. Nine cases out of 33 were completely successful with one injection, another case with two—in all a high eosinophilia (100-200 cells per c.mm.) being noted along with an absolute leucopenia.

"From Professor Ziegler's hospital at Freiburg i. Br. comes an encouraging account of an attempt at auto-serum-therapy. Fifty c.c. of blood were withdrawn, phenolized, and 2.5 to 4 c.c. of the serum injected daily *sub cutem* on the outer side of the thigh. In 14 out of 18 cases improvement was rapid, the temperature falling in 2.5 days, often with marked sweating, coma especially clearing after three or four injections, the patients expressing great relief. The cases so treated were nearly all severe ones, but were all able to be up within four weeks; twice a sudden drop of 2-5° C. was noted with small but not frequent pulse, amenable to camphor. This, as well as the therapeutic effect in general, is to be probably ascribed to bacteriolysis, an explanation given by Hammerschlag as early as 1893. Professor Matthes, of Marburg, is working with a trypsin solution of typhoid bacilli filtered clear as an immunizing agent, which has already given encouraging results with guinea-pigs. Writers all assume that the merits of the prophylactic inoculation are still on trial, and that it will still be long before exact figures are available. Of immediate effects the percentage of serious harm is very low. Under Professor Penzoldt at Erlangen, out of 4000 injections in 1780 persons only 6.8% had fever above 38° C. and 0.2% above 39° C. In two cases, aged 28 and 33 years, thrombosis occurred once in the forearm, and once an embolic thrombus of the leg. In a third case, a few hours after the second prophylactic injection, the temperature rose to 39.6° C., followed by typical splenic enlargement, roseolar rash, and bronchitis and exitus 14 days later from intestinal hemorrhage. Menzer had already recorded a case with diarrhea and roseola, and Professor Penzoldt inclines to the assumption of an aggressin action of the dead bacilli on a concurrent living infection. At Strassburg Professor Schlesinger, out of 1340 injections, never saw any serious local reaction; after the three injections 5%, 3%, and 2%, respectively, were unfit for service on the following morning, the indisposition differing from influenza in that improvement was almost always noted within 24 hours. Urticaria was not very uncommon, and in 5 to 8% the spleen was enlarged. Professor Weichardt (Erlangen) finds that local reaction is slighter with the newer vaccines sterilized at a lower temperature, there being no appreciable risk in their employment, as 0.5%

phenol kills any living bacilli in the vaccine within 24 hours. Smaller doses at longer intervals will probably immunize as fully as large ones at shorter intervals."

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING MAY 29, 1915.

CONTRIBUTIONS.

Dr. J. E. Talley, Philadelphia, Pa..... \$ 10.00
Dr. Leonard W. Ely, Palo Alto, California... 5.00

Receipts for the week ending May 29.....\$ 15.00
Previously reported receipts.....6993.50

Total receipts.....\$7008.50

Previously reported disbursements:

1625 standard boxes of food @ \$2.20..\$3575.00

1274 standard boxes of food @ \$2.30.. 2930.00

213 standard boxes of food @ \$2.28— 485.64

Total disbursements.....\$6990.84

Balance \$17.66

F. F. SIMPSON, M.D., *Treasurer*,
7048 Jenkins Arcade Bldg.,
Pittsburg, Pa.

Owing to the fact it is not permissible to ship salt into Belgium, a recent change in the price of the boxes of food from \$2.30 to \$2.28 caused an error in the report of May 1st. The correction is made in this issue.

A number of contributors have suggested that the full address of the Treasurer be published with the reports, as many are still in doubt as to where to send contributions for the Belgian profession.

RECENT DEATHS.

DR. JOHN RICE ELDRIDGE, who died recently at Berkeley, California, was born in Milford, Mass. He received the degree of A.B. from Harvard in 1888, and that of M.D. from the Cooper Medical College of California in 1894. He subsequently practised his profession in San Francisco, Fresno and Berkeley. He is survived by his widow, one daughter and one son.

DR. GEORGE H. HUTCHINGS, who died on May 30 at Woburn, Mass., was born at Charlestown, Mass., in 1840. He studied medicine at the New York and Cincinnati Eclectic Medical Colleges, from the latter of which he received the honorary degree of M.D. in 1861. He practised his profession successively at Wilmont, N. H., Boston, Townsend and Woburn, Mass. He is survived by his widow and by one son, who is also a physician.

DR. JAMES H. JOYCE, who died recently at Salem, Mass., was born in that city in 1880. He received the degree of M.D. from the Tufts Medical School in 1903 and since that time had practised his profession in Salem, where he had served as city physician. He is survived by his widow.

DR. SUMNER CARRUTH SAVILLE died at Cambridge Mass., on May 27, aged 48 years. He was a native of Boston and a graduate of Harvard in the class of 1891 and of the Harvard Medical School in 1894. He had an office at 34 Newbury Street, Boston. He was unmarried. Dr. Saville was a Fellow of the Massachusetts Medical Society and a member of the Boston Medical Library and the Harvard Medical Alumni Association.

THE SHATTUCK LECTURE.

AN ANATOMIC AND MECHANISTIC CONCEPTION OF DISEASE.*

By JOEL E. GOLDTHWAIT, M.D., BOSTON.

THE subject which has been announced for this, the twenty-sixth lecture given under the conditions of the bequest made by Dr. Shattuck, was chosen after much consideration as being of broad general interest and as having to do with the fundamentals of medical knowledge. It seemed possible that such a consideration might be of sufficient importance to be worthy of the occasion, and if it be so considered it will be a satisfaction to me, as being a slight return for the honor which you have conferred upon me in selecting me as your speaker.

The basis of that which is here presented is work which has been carried on for a number of years in the attempt to find the cause of the chronic disease conditions for which the orthopedist is consulted. A fairly exhaustive pathologic investigation failing to show more than the nature of the lesion, with similar experience from the bacteriologic and the biochemical investigations, led to the study of the fundamental anatomic conditions existing in patients afflicted with these diseases, with results which have been increasingly more suggestive the farther the study has been carried.

* Delivered before The Massachusetts Medical Society at Boston, June 8, 1915.

It is this study which represents the first part of this paper and which has been reported in part from time to time by the writer in articles which have called attention to the variations in the formation of the viscera and skeleton, as well as to the peculiarities of the particular function.¹

In this investigation it soon became evident that the anatomic formation described in the textbooks as normal to the human being, rarely exists in the individual having the common chronic disease, and in the study which naturally followed not only were the different anatomic types recognized, but in the hope of better understanding the variations found, the structure of the lower orders of mammals was studied with considerable care.

Recently, with the assistance of Dr. John Bryant, not only have these anatomic findings been verified in connection with his work,² but the literature has been carefully examined and the fact that most of the elements to be presented have already been recorded has served to increase the belief that the observations here stated are correct and that the appreciation of these elements is absolutely essential if any impression is to be made by our profession upon the great field of chronic medicine which today represents such a reproach to us.

The fact that no more has been accomplished as the result of these numerous contributions to medical literature in the past is probably due to the fact that most of the work is fragmentary in character and that it is only by piecing together many of these separate contributions that the significance of each with the great importance of the whole is realized.

It is the hope, that in this communication, the independent observations which have been carried on by the speaker, may be so strengthened by the similar findings of these other observers that this knowledge may be generally applied to the study of our patients.

In such an investigation, while the first thing that impresses one is that the so-called normal type of human being rarely exists in the chronic patient, the second is that the variations from the normal group themselves into two general types from which again there are many variations, but that if the original type is appreciated the variations from it are easily traced and understood.

In order to better understand the types to be described, it is well to consider for a moment that which from the textbooks we call normal.

Normal Human Type. (Figs. 1, 2 and 3).

FIG. 1.
The normal human type.

There is very little variation to be found in the works of anatomy in that which is called normal. The torso is of moderate length and of moderate breadth. The thorax is full, and moderately rounded, the upper abdomen is rounded and in circumference about the same as that taken just above the nipple. The costal border is formed in an angle from 70° to 90° . The diaphragm is high and there is generous space under the ribs for the viscera. All of the abdominal viscera, except the lower portions of the colon with the sigmoid and part of the small intestine, are above the umbilicus. Around the viscera and representing a definite part of their support, as well as giving much protection from

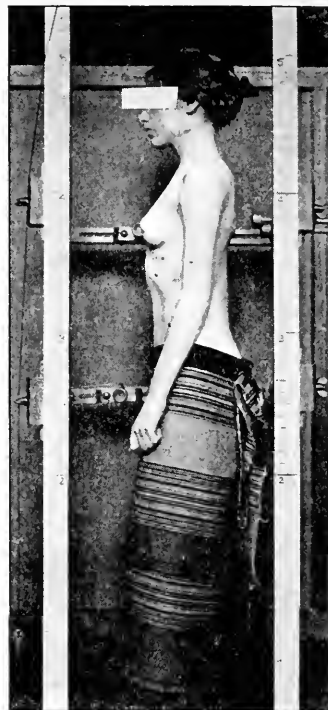

FIG. 2.
Normal human type, showing the normal inclination of pelvis, normal elevation of ribs, normal position of shoulders, etc.

FIG. 3.
Normal human type, showing the moderate breadth of the body.

trauma to the sympathetic nerves, ganglia and blood vessels, are well-defined masses of fat. The lower abdomen is flat, while the upper abdomen is firm and rounded, there being no marked

depression under or inside the edge of the ribs. The spine shows a mild curve forward in the lumbar region, with the inclination backward from the mid-lumbar, this resulting in the general inclination of the abdominal cavity of 30° downward and forward from the perpendicular. The pelvis, in the axis of its cavity, is inclined downward and backward about 60° from the perpendicular so that the two axes form nearly a right angle.

Of the special viscera, the stomach is of the pear shape, and is placed well up under the ribs, occupying the uppermost part of the abdominal cavity upon the left side. In this position the discharge of its contents into the duodenum requires but little effort.

The small intestine is about 20 feet in length, is of good calibre and muscular tone. The large intestine, of five to six feet in length, is adherent to the posterior abdominal wall upon the right side until it reaches the region of the liver, when it turns forward and inward, crossing with a slight downward sag to the splenic flexure well up in the left side of the abdomen behind the stomach, from which point it is again attached to the posterior wall (retroperitoneal) until it reaches the sigmoid, where, after a few turns, it becomes the rectum. The transverse part of the colon is attached to the liver upon the right side and to the stomach in the center of the body and upon the left side. The stomach and liver are naturally attached to the diaphragm, and the suspensory ligament of the diaphragm is the pericardium, especially the right side, which is finally attached to the anterior part of the low cervical spine.

In the upper part of the abdomen is the solar plexus of the sympathetic system, the ganglia being so placed that when the organs are in their proper position there can be the least possible pressure upon or irritation of them.

These and many other elements are described in the anatomy as normal, and while this type does exist very commonly among those who are well, nevertheless, among the individuals who consult the physician, especially with chronic disease, this type is not often seen, and it must be hard to understand the conditions present in our patients unless their special structural formation is known.

Of the variations from the normal there are two well marked types which are easy of recognition and are here described.

Splanchnoptotic (Glenhard); *Congenital Visceroptotic* (Goldthwait,¹ Smith³); *Carnivorous* (Treves,⁴ Werner,⁵ Bryant²); *Hyper-ontomorph* (Bean⁶); *Macroscelous* (Montessori⁷); "Narrow-Backed" (*Industrial*). (Figs. 4, 5, 6 and 7).

The type of human being for which the above and other terms have been used is essentially different from the so-called normal in most of its characteristics. The whole figure is lighter, not

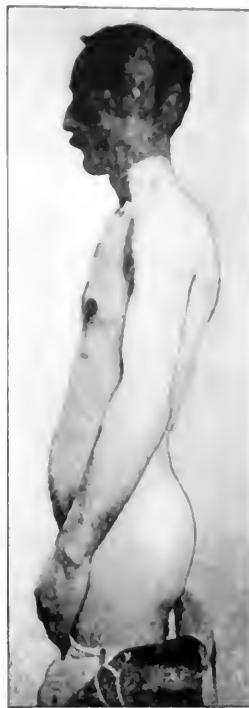

FIG. 4.

The slender congenital visceroptotic or carnivorous type, showing the proportionately greater length of body, the increased low lumbar curve, forward inclination of pelvis, forward position of the shoulder, flat chest, prominent lower abdomen, narrow upper abdomen, forward position of head, etc.

FIG. 5.

Slender type, showing the same features as in Fig. 4, except an increase in the forward inclination of the pelvis and more marked forward position of the shoulder, and a more completely flattened chest.

FIG. 6.

The congenitally visceroptotic type, showing the extremely slender back.

FIG. 7.

The slender or congenital visceroptotic type in child, showing the same general characteristics as in adult.

only that there is less fat, but the skeleton is lighter and more slender in form. The skin is soft and delicate. The hair is more abundant in

the usual places and frequently shows on parts where it is not normally seen. The individual is usually either tall and slender or small and delicate. The head is proportionately large, the face and jaw are narrow. The palatal arch is high. The adenoid and tonsillar tissue is apt to be excessive. The ears are usually large and prominent, projecting outward and forward. The torso is longer in proportion than the so-called normal and is also narrower. (Fig. 6). The increased length is partly in the thorax, but chiefly in the lumbar region. The ribs are usually longer than is normal, the tenth rib is almost always free, and when seen in the adult, the downward inclination of the lower ribs is very marked, they at times, in the standing position, touching the upper part of the ilia. The spine is smaller in size than normal and the lumbar vertebrae are more like the so-called normal dorsal vertebrae in shape, the body being of about the same width laterally as it is deep antero-posteriorly. (Fig. 8). There are fre-

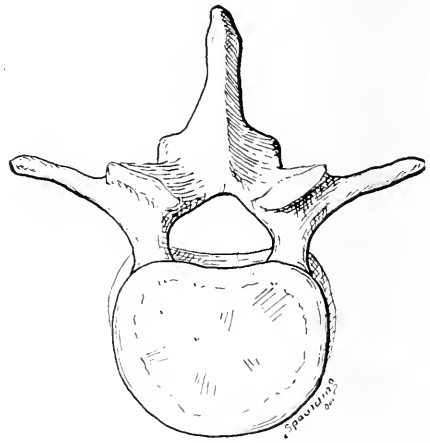

FIG. 8.

Lumbar vertebra in slender type, showing small body to the bone, with slender laminae and with flat articular processes.

quently six vertebrae in the lumbar region with the full number of sacral vertebrae, this being one of the reasons for the greater proportionate length of the body. The transverse processes are small and short and the articular processes are usually flat (not crescentic). Because of this formation, the lumbar spine is much more flexible than the normal type and it is this anatomic type from which the fancy dancer, the hurdler and acrobat are developed.

The thorax is of fair size, the lungs are apparently smaller than normal, and the smaller size of the heart is easily demonstrated by the x-ray. The abdominal viscera have peculiarities in shape and attachment unlike the normal human. The stomach is long and tubular, instead of the normal pear shape. Its attachments are less firm, so that the possible downward displacement in standing is much greater than normal. The duodenum is usually attached to the normal position, but this is not constant. The small intestine as a whole is much shorter than normal,

containing from 10 to 15 feet instead of the normal 20 feet, the walls are less thick, and the lumen smaller. According to Bean,⁶ the length is from 12 to 15 feet; Swain⁸ from 10 feet up; Bryant² from 10 to 15. The mesentery is longer than normal, so that in standing the small intestine is almost entirely in the upper pelvis or lower abdomen. The large intestine is shorter than normal, from three to five feet, and much more mobile. Almost always upon the right side there is a free mesentery so that this portion may change its position easily, and frequently the left side also has a mesentery, so that in the upright position the entire colon lies below the crests of the ilia. The most common condition, however, is with the normal retroperitoneal position upon the left side with the right side free. The transverse part of the colon is usually attached to the stomach, which means that it will be found below the position of the stomach, even though the stomach may have its lower border in the pelvis. With the transverse colon, while it is usually attached to the stomach, it frequently has an entirely free mesentery, as is natural with even the purely normal type in the early embryologic state. In this type the vermiform appendix is usually well developed, while in the next type to be described the appendix apparently is much less developed, which may in part explain the common occurrence of appendicitis in the thin, slender individuals. With this type of anatomy there is very little retroperitoneal fat, palpation of the flanks is easy, the kidneys are naturally mobile, the liver is smaller and is more loosely attached than normal.

It is this type of anatomy in which the scaphoid type of scapula (Graves⁹) is found. The muscles are formed of the long and slender fibres. The extremities vary in length as one would suppose in studying comparative anatomy, the carnivora at times having very long legs, as the greyhound, or very short legs, as the otter, but they are usually longer than is considered normal and both arms and legs are relatively slender. The feet are slender and often of unnaturally high arch. The hands are slender but long, the fingers being very slender and tapering. While this type is usually thin, at times there is much accumulation of fat. If this is present it usually develops rapidly, disappearing at times equally rapidly, and the fat is always soft with very little connective tissue and suggests poor health.

Herbivorous (Treves,⁴ Werner,⁵ Bryant²): "Broad Backed" (*Industrial*); *Meso-ontomorph* (Bean⁶); *Brachyscelous* (Montessori⁷). (Figs. 9, 10, 11 and 12).

Upon the other side of the normal human type, and in marked contrast to the slender, carnivorous type, is the heavily built, broad backed type of human, in which so many of the characteris-

FIG. 9.

The heavy or extreme herbivorous type, showing the large, heavy build of the body throughout, the relatively straight position of the pelvis, the backward bend occurring in the upper lumbar region rather than in the low lumbar, showing the round-shaped head, flat ear, broad neck, with the shoulder well back on the thorax.

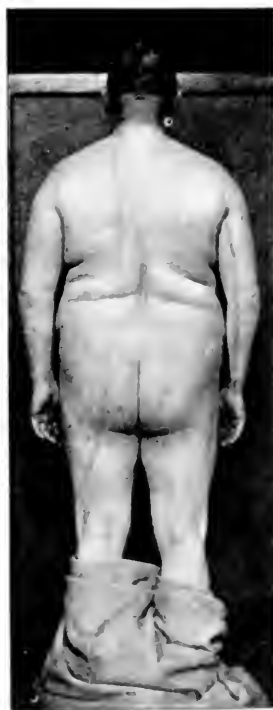

FIG. 10.

The broad backed or herbivorous type, showing the extremely broad body.

FIG. 11.

The broad, heavy type, showing all the general characteristics of Figs. 9 and 10.

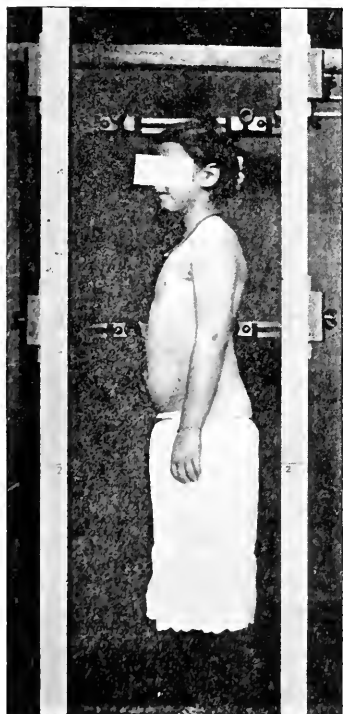

FIG. 12.

The broad, herbivorous type in the child, showing the same general characteristics of position of pelvis, curves of spine, position of shoulder, high chest, prominent upper abdomen, broad face, flat ears, as in Figs. 9, 10, and 11. The position of hyperextension at the dorso-lumbar juncture is well shown in this figure.

ties are similar to those found in the herbivorous creatures that this term has been used for their designation.

In this type the body is built upon much heavier lines throughout. The skeleton is larger in proportion and heavier in structure. The muscles are large with coarse fibres. The skin is coarse with scant growth of hair, which is lost early. There is an excess of fat throughout the body, but this is bound together with much connective tissue so that the flesh feels hard and firm in contrast to the soft, flabby feel such as is peculiar to the slender type. The head is round, the face is broad, the jaw is square, the ears are usually placed flat against the side of the head, and as a rule are not very large. The neck is short and thick, the shoulders are broad and square. The body as a whole is broad and relatively short. The chest is larger both in the lateral and antero-posterior diameters than the normal. The diaphragm is high, the costal border is formed in a broad angle, rarely less than 90° and sometimes more. The tenth rib is usually attached to the conjoined cartilages in front and the last two ribs are relatively short. The lumbar region is short, partly because of the frequent presence of only four lumbar vertebrae and partly because the sacrum is set well down between the wings of the ilia. The abdominal cavity is broad and deep. The stomach is large and pear shaped. The duodenum is attached as in the normal. The small intestine as a whole is much longer than the normal, and ranges from 25 to 39 feet (Bryant²). The large intestine is larger and longer than normal, from five to eight and one half feet (Swain³), with the retroperitoneal attachment of the ascending and descending portions, the added length showing in the longer transverse portion and in the sigmoid. The liver is large but well up under the diaphragm. There is much retroperitoneal and general abdominal fat so that the kidneys are well held in place and the sympathetic ganglia are well protected.

The joints in this type are much less flexible than in either of the other types, the individuals as a whole being strongly and heavily built.

The spine is broad and heavy throughout, but in the lumbar region this is especially noticeable. The lateral diameter of the vertebral bodies in this region is considerably greater than the antero-posterior (Fig. 13), the articular processes are strong and large and almost always of the crescentic type. The transverse processes are long and broad, and the process of the last lumbar frequently forms an articulation (the lumbo sacral transverse articulation) with the top of the sacrum. The long and broad transverse processes upon the lumbar spine are similar to that which is found in the herbivorous animals and which produces the lateral rounding of the back seen in all the hoof footed creatures. This formation apparently furnishes protection

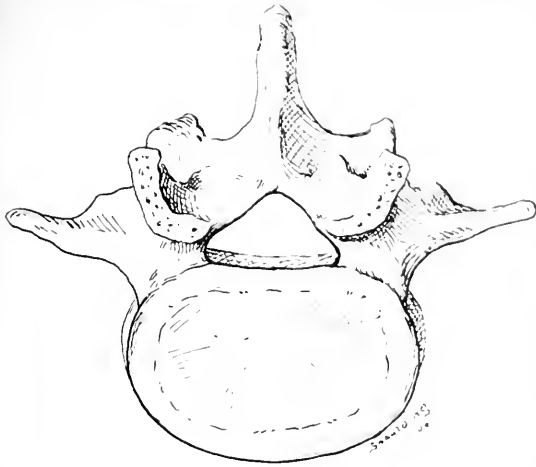

FIG. 13.

Lumbar vertebra of heavy or herbivorous type, showing the broad body and the heavy laminae.

and attachment for the many coils of intestine in the abdominal cavity.

Because of the shape of the vertebrae and the character of the articulation with the sacrum, there is less lumbar curve forward than is present in either of the other types (Figs. 1 and 2 and 4 and 5), and the forward inclination of the pelvis is also less. The axis of the sacrum is more nearly perpendicular. In this type not only are the wings of the ilia higher than in the normal so that the transverse process of the last lumbar articulates not only with the sacrum, but also at times with the ilium, and in a few cases the transverse process of the vertebrae above also rests against the ilium or has strong ligamentous attachment to it.

The extremities in this type vary in length as one would expect from the study of the comparative anatomy of the herbivorous creatures, but are always heavy. The legs are large, the knees are straight, the feet are broad in proportion to length, and the arch, while it may be very strong is usually quite low. The arms are heavily built, and the shoulder attachment is well back upon the thorax, giving the square shoulder appearance. The hands are broad and "chubby," both in the palmar portion and in the fingers.

Spinal Motions of the Different Types.

Because of the different structure of the bones of the spine, the motions must vary. In the normal, in bending forward the spine is well rounded and laterally there is some motion beginning at the lumbo sacral juncture and extending up to the low dorsal region, while in backward bending considerable motion is allowed. In the carnivorous type this is similar, only the amount of motion is much greater, as would be expected from the description of the bony formation of the type. With the herbivorous type, as must be apparent, the spinal motions are much less free. In this, the forward bending is made largely at the hips, there being but little in the spine. Laterally practically

no motion is allowed except at the dorso lumbar juncture, none whatever being allowed in the low back if the lumbo sacral transverse joint exists. If this exists upon one side, no motion at that region will be allowed to that side, while to the other side slight motion may be allowed. In backward bending very little is allowed, and if the lumbo sacral transverse joint exists, none will be allowed at the lumbo sacral juncture.

Such are the three general types which are common in the human family, and the fact that such types exist there can be no question if the passersby upon the street are noticed, even if one is not willing to accept the statements of those who have studied anatomy in this way. The thin carnivorous person is there side by side with the broad, full faced herbivorous person, with the normal human also present, and the characteristics are so distinct that nothing more than the glance is necessary to recognize the special form. The characteristics are equally apparent in childhood as in adult life, as is indicated by the accompanying illustrations.

The difference in the types and the fitness of each for different forms of work is already known, and a person who is at the head of an organization employing large numbers of laborers states that when an order for laborers is given it is expected that it will indicate so many "broad backs" or so many "narrow backs." The "broad back" is fitted for the ordinary heavy work, while the "narrow back" is fitted for the work requiring greater agility, such as climbing poles or trees, prospecting, running the lines, etc. The "broad back" carries the heavier load, but the "narrow back" carries his lighter load more rapidly.

The difference in the anatomic types is also recognized, consciously or unconsciously, in art, and nothing can be more perfectly normal than the early (not always the late) Greek figures, or Michael Angelo's "David," or William Hunt's "Bathers." The type which Rubens almost always depicts is the heavy, full blooded herbivorous type, while the slender, carnivorous type is the one depicted by Botticelli and Fra Angelico, or by Puvis de Chavannes of the modern school.

The fact that such types exist, but that they also have different characteristics which should be recognized in their training, is shown by Dr. Montessori in her book, "Pedagogical Anthropology," in which the pictures of the types are shown and the intellectual characteristics discussed.

In athletics also the appreciation of the different physical types is clearly understood. The hurdler or the runner is usually of the normal or the slender type, while the hammer thrower, the shot putter or the wrestler is usually of the heavy type. The heavy men are usually found in the line of the football team, while in the backfield the more slender and agile persons are found.

The types exist, and in a very large number of instances the types are pure, the carnivorous being carnivorous throughout, the normal human being the normal human throughout, and the same is true of the herbivorous. In other instances, however, the types are mixed, and it is here that the greatest difficulty exists in understanding the symptoms or in planning the treatment. A carnivorous type in general build and viscera may have an herbivorous type of spine, a combination which is quite common in women. A carnivorous type of stomach and intestine may exist with a normal liver and kidneys, in so far as shape and position are concerned. The normal type in general may have one or many of the characteristics of either the carnivorous or the herbivorous. The herbivorous type may show characteristics of either of the others and probably the most common variation in this type is the smaller spine and the imperfectly attached colon, but of the full length.

That such differences exist in the anatomic formation of members of the human family there can be no question, and it is not unreasonable to expect such differences if the biologic principles of the development of the race are considered. The human being as the highest type of mammal naturally inherits something of the strains which have shown themselves in the various species through which the advance of the mammalian group has occurred, and it is only by studying comparative anatomy that the various differences of type can be understood.

From the purely medical point of view the recognition of these different types is important since the types apparently carry their own potential of disease. The tuberculous and the infections in general, the nervous diseases and acute mental disorders, the hyperglandular disturbances, the progressive anaemias, the atrophic arthritis, many of the intestinal disorders, etc., naturally are associated with the slender type. The arterio-sclerosis, hypertrophic arthritis, gout, diabetes (not the insipidus), chronic disease of the kidney, gall stones, the prostatic hypertrophy, the degenerative mental disorders, etc., are common to the heavy type. The suggestiveness of this in treatment must be obvious.

Habits of Posture in the Different Types and the Effect upon the Physiology.

Not only has the study of the chronic patient shown that the different anatomic types exist, but that this alone can hardly explain all the phenomena. The more the problem is studied, the more evident it becomes that the life of the creature as an erect biped is a very different thing from that of the quadruped in so far as the function of the different parts is concerned.

One of the penalties that the human being is forced to accept in his being the highest type of mammal, is that in locomotion, with the body used as an erect biped, gravity is constantly operating to drag the organs downward out of

their normal position, as well as to draw the upper part of the body downward and forward into positions which must mean strain and weakness. This element, together with the anatomic form, seems many times sufficient to cause the conditions seen in chronic medicine.

The counteracting element, to offset such a handicap and prevent the race from being irreparably harmed, is the intelligence with which the human being is peculiarly endowed. The real purpose of such a paper as this is to help in the training of this intelligence so that life may be a period of wholesome, healthy development, with the fullest possible energy available for whatever stress to which the individual may be subjected.

The way the body is used is of quite as much importance as the structure of the body itself. Either type has the potential of good health if used rightly, but each has an equally definite potential of disease if the proper relationship between the many parts is not preserved. With the normal type it is naturally easier to maintain this relationship, but the possibility of not maintaining it is painfully apparent as one goes among one's fellow men. With the other types the special postures or the form of the maladjustment naturally differs as one would expect from the structure.

Since the pathologic changes which are seen are apparently due very largely to this imperfect adjustment of the parts, it is of the first importance that the postures or special elements of maladjustment which are peculiar to the different types should be appreciated. It should also be remembered that with the chronic patient the large majority of the cases fall into the slender, congenital visceroptotic type or the broad, herbivorous type.

The Normal Human.

When the body is used rightly (Fig. 1 or 2), all of the structures are in such adjustment that there is no particular strain on any part. The physical powers are at their best, the mental functions are performed most easily, and the personality or spirit of the individual possesses its greatest strength.

When used rightly, or fully erect, the feet, knees, hips, spine, shoulders, head and all the portions which represent the frame of the body, are used in balance, with the greatest range of movement possible without strain. In this position the chest is held high and well expanded, the diaphragm is raised, and the breathing and heart action are performed most easily. The abdominal wall is firm and flat, and the shape of the abdominal cavity resembles an inverted pear (Forbes, Williams¹⁶) (Fig. 14), large and rounded above and small below. The ribs have only a moderate downward inclination. The subdiaphragmatic space is ample to accommodate the viscera. In this position, also, there is no undue pressure upon, or interference with, the pelvic

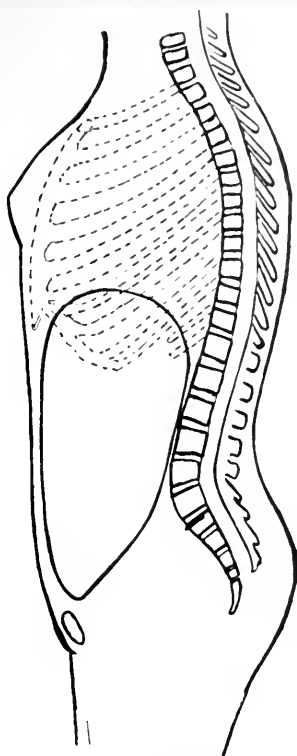

Fig. 14. (Williams.)

viscera or with the large ganglia at the back of the abdomen and in the pelvis.

Relaxed Position.

If the body is drooped or relaxed, so that the shoulders drag forward and downward, the whole body suffers, the weight is thrown imperfectly upon the feet, so that the arch must be strained; the knees are slightly sprung, which shows by the crepitating joints; the pelvis is changed in its inclination, with strain to the sacro-iliac joints and low back. The increased forward curve of the upper dorsal spine results not only in strain to the intraspineous ligaments, but also forces the shoulders forward, with frequent irritation of the bursae about the shoulder, or compression of the brachial plexus, with pain and neuralgias in the arms, while the craning forward of the head must result in strain to the posterior part of the cervical spine.

In this position the chest is necessarily lowered, the lungs are much less fully expanded than normal, the diaphragm is depressed, the abdominal wall is relaxed, so that with the lessened support of the abdominal wall, together with the lowering of the diaphragm, the abdominal organs are necessarily forced downward and forward. When this occurs the possibility of mechanical interference with the function of the organs is not difficult to imagine, and it becomes apparently a mere matter of chance which organ is affected.

The thing that is important in the interpretation of the many symptoms which the patients

describe is that the body is most intimately related in its different parts so that no one part can be used wrongly without the body as a whole suffering. For this reason if these various groups of symptoms are to be considered as purely local and distinct lesions the results are sure to be unsatisfactory. The body as a whole should be considered and not just the chest or the abdomen or the feet or the back or any one part, and it should be considered with reference to use in the different positions in the routine of life, especially those which are maintained for long periods, the occupational postures. In sitting it is perfectly possible to sit so that the trunk is in practically the same shape and with the different parts in practically the same relation, as they are when the body is used fully erect. At the same time in sitting it is very common to have the body markedly drooped, so that the body is rounded forward with the lumbar spine entirely reversed in its curve, with the ribs low, so that the thorax practically telescopes into the abdominal cavity. When such a position is studied with reference to the mechanics of the function of the organs the wonder is not that disturbances result, but that the disturbances are not more marked.

In such a study of the mechanics of the physiology, the positions assumed when the patient is lying down should be investigated. It is perfectly possible to produce practically the same effect upon the shape of the body and upon the thoracic and abdominal cavities that is present when the patient is sitting in the slouched position, if when lying down several pillows are placed under the head and shoulders, as is so frequently seen. In such a position naturally the breathing and circulation, the digestion, and the other physiological functions cannot go on rightly, and the restless, dreaming sleep is many times due to no other cause than this.

The importance of the proper relationship of the parts should be borne in mind under all conditions, and especially at the times of occupation or when the postures are assumed for continuous periods. It is under such conditions that naturally the greatest harm results, and it should be remembered that irrespective of the type, the postures which are assumed as the body is used determine very largely whether the individual is to be well or ill. *The most perfect, anatomically, may have the poorest health, while the most imperfect, anatomically, may have good health.* Fig. 15 is of the normal type as is shown when the body is held erect (Fig. 16) but the posture commonly maintained (Fig. 15) suggests very little of normal vigorous health.

The postures which are assumed by the other anatomic types are perfectly characteristic, so that once they are appreciated, the posture itself very largely indicates the type of anatomy to be found in the individual. It is always to be remembered that while the type is present at

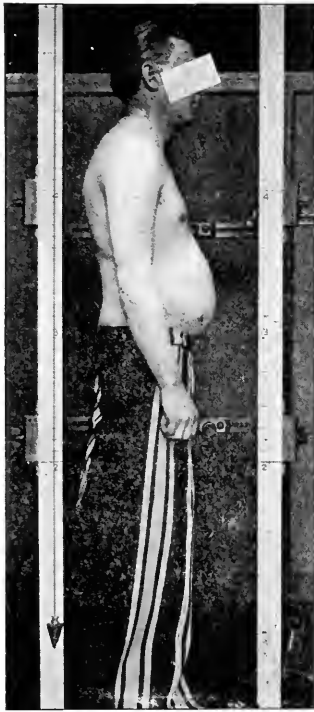

FIG. 15.

The normal human type, with acquired habits of bad posture, with marked visceroptosis, drooped shoulder, etc.

FIG. 16.

The same case as Fig. 15, except that the body is held at attention, showing the way the viscera are drawn up under the diaphragm, giving the normal lines of the body when the body is held erect.

the time of birth, that the extreme characteristics which are seen in adult life are largely the result of stretch and strain due to the downward

displacement which is the rule if the body develops without guidance. As long as the child remains a quadruped, as it is in the first two or three years of life, the special peculiarities are of very little concern, but as soon as it begins to assume the erect posture for long intervals the peculiar postures begin to show and the symptoms which naturally result therefrom begin to develop.

The Congenital Visceroptotic or Carnivorous Type.

In the slender type, while the ideal standing position is the same as with the normal human, the natural position which will be assumed is one in which the general relationship of the parts is much disturbed (Figs. 4, 5 and 7). In this type the chest is flat, the usual standing position being with the chest at full expiration so that all breathing is done from the low point. The sternum is more nearly perpendicular, instead of the forward inclination as is normal. The costal border is inevitably narrower than in the normal type, the angle being usually under 45° while at times in adult life it is so slight as to be hard to insert the fingers between the costal cartilages of the two sides. Because of this position of the ribs, the upper abdomen is naturally very small and the abdominal viscera must be in a different position from that seen in the normal type. The general shape of the abdominal cavity resembles the normal pear (Forbes, Williams¹⁶), large below and narrow above. (Fig. 17). Because of this the liver is displaced downward and it is usually rotated to the right, so that the right border is frequently below the crest of the ilium. The retro-

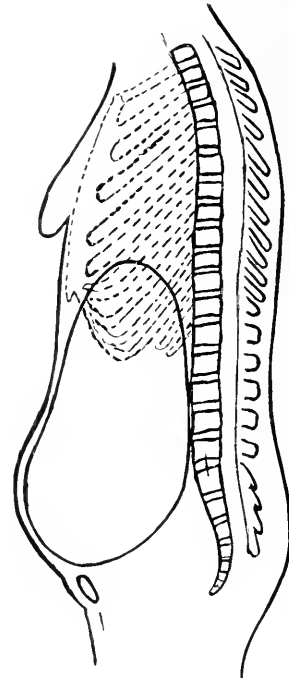

FIG. 17. (Williams.)

peritoneal fat is practically entirely lacking, with the result that the kidneys are usually mobile, the position occupied depending entirely upon the position assumed by the individual at the time of examination. Because of the absence of the retroperitoneal fat, the sympathetic ganglia and the large blood vessels must lie unprotected upon the anterior part of the spine, and it is not improbable that the changing positions of the organs, in the changing positions of the body, must at times lead to irritation or harmful pressure of these ganglia or vessels. The same thing is probably true of the adrenals, which being unprotected by fat pads, must be pressed upon and irritated more than is normal, this mechanical disturbance possibly explaining the peculiarity of the structure of the adrenal in this type of anatomy, which has been described by Dr. Bryant.

In this type of anatomy, since the ribs are lowered in front, the diaphragm must be lower than is normal, and this is increased by the drag of the loosely attached stomach, liver and colon. Because of this, the movement of the diaphragm in respiration must be less than normal, with, at times, practically no movement whatever showing in the Roentgenological study. The effect of this upon the breathing, as well as upon the circulation, especially in the large abdominal veins, to say nothing of the function of the other organs, must be very apparent.

The constant position assumed by this type is with the body inclined backward from the low lumbar region, making a sharper curve in the low spine than is normal, the spine above this point being relatively straight to the upper dorsal region, from which point it bends sharply forward to the midcervical region, where it bends backward again to make the upright position of the head possible. (Figs. 4 and 5). The general impression created by such a position when the individual is dressed is often that of being quite erect. In this position with the ribs low in front there is imperfect support for the shoulders, so that they are drooped forward (Figs. 4, 5 and 18), the scapulae being rotated outward at the top, so that their long axis is much more oblique than normal. In this position the upper part of the scapulae does not rest against the ribs, and since the position exists in childhood when the bones are soft, the unsupported upper part usually is flexed forward, this flexed portion rubbing over the ribs when the shoulders are extended and gives rise to the sensation of crepitation so commonly felt. This irritation if continued naturally causes the pain so frequently referred to this region. With this general posture there are two regions of the spine, the low lumbar and the low or midcervical, in which the degree of hyperextension is greater than is normal, and since in hyperextension the posterior portions of the vertebrae, must be brought closer together than is normal, and since the foramina through which the nerve

FIG. 18.

The slender, congenital viscerotonic or carnivorous type, showing the forward position of the shoulder, with marked rotation of the scapula. In this position the head of the humerus is lowered and rotated inward so that it rests against the second rib, and the possibilities of crowding the vessels of the arm or the nerves of the arm leading to the circulatory disturbances, neuritis, or neuralgias of the arm, are evident.

roots pass are posterior to the point of motion, it is obvious that in this position the foramina must be narrowed. Since this position is the habitual one with this type it is not impossible that some of the little understood symptoms referred to the arms and legs (the parts naturally supplied with sensation and motor control from these two hyperextended regions) or some of the circulatory disturbances of the spinal cord may be due to this anatomic position.

With this hyperextension of the lumbar region and the backward inclination of the upper body, the longitudinal axis of the abdomen is naturally moved backward at the top, but at the same time the pelvis is tipped forward and downward (Figs. 4 and 5), so that its longitudinal axis is moved forward at the top (Fig. 19). The result of this is that the hips stick out at the back more than is normal and the angle formed by the intersection of the two axes, pelvis and abdomen, is less than is normal. In this position the pelvis has its forward inclination changed so that it at times is from 30° to 40° away from the so-called normal position. Naturally in this position the upper part of the sacrum, upon which the spine rests, is moved forward and downward and the weight of the body constantly tends to increase this forward position with resulting abnormal strain to the sacro-iliac joints. This being the case, it is not surprising that it is in this type of anatomy that

FIG. 19.

Spine and pelvis, with left ilium removed, of slender or carnivorous type, showing the marked forward inclination of sacrum. The weight of body must be thrown upon the front of the sacrum, and naturally leads to sacro-iliac strain or displacement.

the strains and displacements of the sacro-iliac joints are most commonly seen.

With this general peculiarity of poise, the weight is naturally thrown upon the feet wrongly, so that the usual high arched foot is markedly pronated and the knees are sprung, usually with some knock knee.

In considering the mechanics of the viscera, naturally the same conditions as to position or mode of use of the body apply as were indicated with the normal human type. The special thing to be borne in mind in this slender type is that all the disturbances of poise are more easily harmful than would be true with the normal human or the more stockily built types. Particularly is it desirable that the positions assumed at night should be considered carefully. The absence of the posterior abdominal fat pads which fill up so much of the lateral spinal spaces naturally allows the loosely attached organs to drag backward much more than is possible in the normal type. This, together with the lack of protection of the ganglia and the blood vessels upon the front of the spine makes mechanical pressure more easily possible than occurs in the normal. It is not improbable that it is this drag or pressure upon these structures during the periods of complete relaxation in sleep that explains the common subnormal temperature, with the weak pulse, the low blood pressure, and the general lack of vitality which is usually present with this type of individual in the morning. For this reason it is particularly desirable that this type of individual should sleep either face downward or upon the side, so that the drag of the organs tends to pull away from the spine rather than to press

backward upon the spine, as would be inevitable if the back position were assumed. The same possibility of backward pressure upon the ganglia or vessels is to be carefully borne in mind at times of operation upon this type, and the back position after operation be maintained as little as possible unless there is some support planned for the low back and loins.

With this type it should be remembered that good poise is possible (Fig. 20). The same child

FIG. 20.

The same case as Fig. 7, showing the possibility of the erect posture, but showing the marked hollow under the ribs as the result of the low position of the viscera.

as Fig. 7), but that it requires greater effort on the part of the individual and greater patience on the part of the helpers than would be required by the normal.

The Broad-Backed, Herbivorous Type.

With this type of anatomy the harmful disturbances of poise as a rule develop much later in life than with the slender type, because the shape of the spine and the general structure of the body withstand strain much longer than the more lightly built creature. In childhood the general posture is with the body erect and in good poise, not unlike that assumed or considered desirable in the normal type.

With this heavy type the disturbances of posture come about chiefly because of the abnormally large and heavy abdominal viscera. This leads to the backward inclination of the body as the weight of the abdomen increases, but since the formation of the low lumbar spine, with this type, does not allow of backward bending, the

inclination takes place either from the hips or at the dorso-lumbar juncture (Fig. 9). The strain produced upon the low back as the result of the posture may lead to marked sensitiveness at the lumbo-sacral juncture, due either to the crowding of the transverse processes against the top of the sacrum with the irritation of the bursae which so commonly lie between, or to the irritation of the articulations formed by the articular processes, or by the crowding together of the spinous processes with the pinching of the intraspinal ligament. Many of the cases of lumbago are undoubtedly to be explained by such strain.

In this type of anatomy the inclination of the pelvis is never forward more than is normal, but is apt to be thrown backward at the top since the pelvis moves with the low spine, and since the backward inclination usually takes place at the hip joints instead of in the lumbar spine. With such a backward tendency if one of the transverse processes is larger than the other, or if the lumbo sacral transverse articulation exists upon one side, or is more marked upon one side than the other, or if the articular processes are peculiar in shape, so that one is crescentic while the other is broad, it is obvious that with the backward inclination, the body is thrown to the side, with at times a marked lateral deformity. It is in this type that the so-called sciatic scoliosis is so often seen (Fig. 21).

FIG. 21.

The broad backed, herbivorous type with the lumbo sacral transverse joint upon the left side, with strain and irritation of this joint, resulting in marked list of the body, with much pain in the left leg, and partial paralysis of the anterior thigh muscles, the so-called sciatic scoliosis.

The symptoms which would naturally result from this would be pain, not in the sacro-iliac joints as in the other type, but at the lumbo sacral juncture, and especially over the lumbo sacral transverse regions. The referred pain will be along the anterior crural nerve or the distribution of the nerves coming from the lumbo-sacral cord, that naturally being the nerve most commonly irritated as it passes under the transverse processes of the fifth lumbar vertebra.

With this type of anatomy the sternum is always carried high so that the chest is more rounded than in the normal human type and the diaphragm is held high, largely because of the bulky viscera which occupy the upper part of the abdomen. As years go on the heavy organs naturally lead to stretching of the abdominal wall so that the viscera occupy a lower level than is normal, but the degree of sag in this type is markedly less than is seen in the slender type with the loosely attached viscera. It should be remembered, however, that the degree of displacement is not that which determines the severity of the symptoms, and that at times the sag of an inch of an organ may produce more serious difficulty than the sag of several inches.

As the organs sag downward, the ribs, while lowered somewhat, are naturally flared at the bottom because of the high attachment of the organs and the fact that the amount of downward displacement that is possible with them is relatively slight. The antero-posterior diameter of the upper abdomen in this type is relatively but little changed by the drooped position over that which would exist when the body is fully erect. On the other hand, in the slender type the antero-posterior diameter of the upper abdomen is much less when the body is drooped than when fully erect. The costal border in this heavy type of anatomy is always broad and usually is more than 90° rather than less.

With the heavy type the positions assumed when sitting are as a rule much less serious than with the slender type, since the structure of the body as a whole makes the droop much less marked, and since in the sitting position the lower abdomen is partly supported on the upper thigh and the downward drag of the organs thereby somewhat lessened.

The position at night is naturally of importance, and with this type the position upon the face would cause so much backward pressure upon the viscera and structures at the back of the abdomen that probably harm would result. The back or the side position is naturally the best. Since the lumbo sacral region is the part most commonly strained in this type of anatomy, the back ache in this type or the referred leg pains are usually relieved by recumbency, the reverse of this being true with the slender type, in which with the sacral strain the day time is the time of greatest ease, the night being the time of greatest discomfort.

Deductions.

If that which is here stated is correct, and verification of the statements should not be difficult, it means, in the first place, that the teaching and study of anatomy should not only have to do with the normal type, but that the other types should be given similar recognition. The need of this broader anatomic training must be obvious when one appreciates how rarely the physician is consulted by the person having the anatomy as it is commonly taught.

It means, also, that in the study of physiology the elements which are peculiar to each type should be investigated and appreciated. When the elements which are easy of study, such as the gastric secretions, the blood pressure, pulse rate, temperature, etc., vary so markedly with the different types there must be similar and perhaps more important variations in the other features which are part of our physiology. To study all individuals from the same point of view must lead to much confusion and explains in part the different reports which are made of seemingly similar investigation. With the types so widely different it is not difficult to believe that there is wide variation in the function of the different parts. The physiology as a whole should be studied with this in mind. The temperature, blood pressure, and other elements of this sort should be observed, but also the problems, such as the mechanics and peristalsis of the stomach and bowel, with the time involved in the passage of food from one part to the other. These must vary, and each type should be studied by itself, since it is obvious that study of one type would be of very little assistance in interpreting the symptoms or functions of another. This must be particularly true of the chemical observations and it must be obvious that in beings having so much the makeup of creatures so widely different as the carnivora and the herbivora there is probably enough of difference in the body metabolism as to make such studies of uncertain value unless the anatomic type of the creature studied is stated.

It means that probably in this difference in types is to be found the explanation of the varying effects of the same diet upon groups of individuals. That one becomes fat while the other remains thin, or that one suffers distress while the other thrives upon the same food must be due to something other than the food. The fact with which even the laity is familiar, that meat in gout is harmful becomes a matter of interest when it is realized that the herbivorous type is the one that is subject to gout. Also the fact that a few years ago so many of the nervous invalids were helped by the diet of chopped red meat and hot water of Dr. Salisbury becomes interesting, since this type of patient is almost always of the carnivorous type. It apparently means that while all human beings have elements within them which make possible the digestion of the different kinds of

food, some are digested with greater ease than others, and that this fact at times is of the greatest importance in the interpretation of symptoms and their treatment.

It means in the medical and surgical treatment of our patients that the symptoms should be interpreted in relation to that which is normal for the special type of anatomy represented in our patient, and that the mechanical conditions present in such a type should be carefully studied. A blood pressure, for instance, that would be normal for one type might be dangerously high or dangerously low for the other type. A disturbance of circulation in the legs, the varicose veins, or in the lower abdominal structures, varicocele, etc., should be thought of not as a local condition, but investigation at once started to see what is pressing upon or interfering with the veins above. Correction of sagging organs, or the removal of some pelvic tumor may wholly relieve the mechanical interference with the veins with entire relief to the conditions below. The treatment of the vein itself, since it is treating a symptom only, must necessarily be unsatisfactory.

In thoracic conditions, it means that not only should the disease of the organ itself be considered, but the conditions under which the special organ works be also considered. In the slender type, since the chest is used at full expiration and since the movements of the diaphragm are also restricted, the lungs should not be expected to become strong or to work rightly until the conditions upon which the proper action of the lungs depends are made possible. With the tuberculous patient, which almost always is of this type, it should be made a part of our work to see that the body is so used and supported that the chest is raised, and the drag upon the diaphragm removed, so that the normal rhythm of respiration is possible, as much as to see that the patient is given fresh air. The air cannot get into the lungs unless these mechanical elements are recognized. The same is true of the heart action, if the chest is low, and the diaphragm depressed so that the suspensory ligament, which is the pericardium, is stretched. Not only must the heart labor at a disadvantage from its immediate environment, but the interference with the diaphragmatic action must be of much importance, and for only one illustration, the unloading of the abdominal veins, which is dependent so much upon the movement of the diaphragm, must be disturbed. When the mechanics of the heart action is considered one is not surprised to find such work as the article by M. Herz¹⁰ upon "Interference with the Heart Action by Stooeping," reported.

In the abdominal conditions it means that they should be given proper anatomic and mechanistic consideration. It may be that the individual is simply receiving food that is designed for an entirely different type or it may be that the organ or organs are so mechanically

out of adjustment that the normal function is impossible. The imperfect action of the liver or the formation of gall stones may be due to mechanical interference with the structures upon which the function depends. The fact that gall stones so commonly are found in the heavy type, while the cystic bladder is so commonly seen in the slender type, probably means something which has both a physiologic and a mechanistic significance. The inability of the stomach to empty itself, or the variations in the character of its secretions, may be due to the position of the organ itself or to interference with the vessels or nerves supplying it. The function of the bowel, both large and small, may be good or ill in proportion as its structure is normal or its position is correct. Kinks may occur, but it should be remembered that while some are serious and require surgical interference, that many times if the mechanistic features are appreciated, that the kink can easily be released, while if surgery is employed, the special kink may be removed but the structural formation is such that other kinks are possible, with a greater probability of their developing because of the postoperative adhesions which are sure to be added to the structural peculiarities. The ulcers of the stomach or duodenum may be due to improper pressure, as has been fully described by Codman.¹¹

It means in the part of the study in which the x-ray is used, that the difference in the position of the viscera that should be present when the body is recumbent upon the side or back, as well as that which should exist when the body is erect, should be fully understood.

It means that with the disturbances of the kidneys, that those which are mobile should be expected as a part of the anatomy of the slender type, and that attempted suture of such organs can hardly be successful unless there is much postural training, since all of the mechanics tend to displace them. In the so-called diseases of the kidneys it should be remembered that albumen and the other abnormal elements are only symptoms of a condition, and may be due to improper demand put upon them by the wrong food, or may be due to some purely mechanical condition. When the anatomic features are considered as well as all the mechanistic features one is not surprised to find such work as Scholder and Weith¹² carried on at Lausanne, showing that in 1254 school children in over 20% they were able to obtain albuminuria by putting the children in certain definite postures. Similar work by Fisehl and E. Popper¹³ upon albuminuria is of additional suggestiveness.

With the presence of sugar in the urine it is not impossible that as well as improper food the pressure of the mobile, heavy organs upon the pancreas, or its blood vessels, may be distinctly causative of the symptom. Certain it is that when one has seen cases in which after

most careful dieting the sugar has persisted and then after supporting the organs properly the sugar has wholly disappeared, it is hard to believe that the mechanistic elements are not of some importance. It should be remembered that the diabetic is almost always the heavy type and that sugar is rarely present in the slender type, except occasionally in childhood, and then only in an evanescent manner. In this heavy type the organs are heavy and are placed in the upper abdomen, while in the slender type they are much lower. One cannot help wondering if the heavy organs by sagging may not crowd the pancreas or the sympathetic ganglia of that region with etiological importance. The supports or postures which are used should be planned with reference to this.

It means in considering the blood diseases, especially the profound anemias, which cannot be explained in other ways, that the position of the spleen or the effect which other organs may have upon its function should be considered. The ease with which the blood supply of this organ could be shut off or interfered with as the other organs move about, must be apparent, while the possibility of the spleen itself being displaced or its vessels twisted, must be equally evident as we come more and more to understand the mobility of the various viscera. The fact that the blood recovery has taken place rapidly after mechanical treatment has been applied, after the previous continuance of the symptoms in spite of the ordinary medical measures, makes it seem probable that to make it possible for the organ to work, is perhaps as important a part of treatment as any other.

It means that with the disturbances of the other abdominal organs that both the anatomic and the mechanistic features should be considered; that the stomach and liver cannot work rightly if the ribs are contracted and narrowed so that there is practically no subdiaphragmatic space; that the pelvic organs cannot work rightly and must be congested if the loose abdominal organs are crowded into the lower abdomen and pelvis.

It means that in studying the mental diseases or the nervous disorders, since with the former the acute conditions are usually seen in the slender or carnivorous type, while the chronic or degenerative conditions are usually seen in the heavy type, in which the arteriosclerotic changes are common, and since also the functional nervous conditions are usually seen in the slender type, that probably the anatomic form is of distinct importance in the understanding of such conditions. It is not improbable that the acquired characteristics, with the mechanical disturbance of the physiology which is to be expected under such conditions, may be of distinct etiological importance.

With epilepsy, the recent literature so strongly suggests that many of the cases are due to gastro-intestinal derangements that it is not un-

reasonable to wonder if by studying the anatomic condition fully, we may not find suggestions that will be helpful in our treatment. From the mechanistic point of view when occasionally one sees the convulsions stop instantly by the mere change of position to that in which there would be less pressure of the viscera upon the ganglia and vessels in the posterior part of the upper abdomen, it makes one question if these mechanistic elements are not part of the complex condition that shows itself in the convulsion.

It means that in studying the disturbances of the internal glands that since the hyper-thyroid conditions are usually seen in the slender type, while the hypo-thyroid conditions so commonly occur in the heavy type, it is possible that in the better understanding of the physiology of the whole body with such an anatomic basis, our treatment of these conditions may be more satisfactory.

It means that in studying such local conditions as the disturbances of the eye, it should be appreciated that the circulation in the eye may be so materially changed by postures which interfere with the blood flow to the head that the shape of the eye is changed, the near sighted eye resulting (Howe¹⁴). In such diseases as cataract, since these commonly develop in the heavy or herbivorous type, as is true of the hypertrophic arthritis, perhaps there is something else to be done other than wait for suitable time for operation. With such understanding of the anatomic types and their physiologic potentials, one is encouraged in such hope by work such as is reported by Connor.¹⁵

With some of the other inflammatory conditions of the eye it is not improbable that the function of the ophthalmologist will extend much farther than the application of the local remedies, but that a kink in the bowel leading to an eye infection or the interference with the circulation in the eye as a result of some local mechanical feature may be the real cause of the trouble and that his greatest function is seeing that these conditions are corrected.

It means, in obstetrical work, that the different types have very different potentials. The slender type of woman is as a rule in better health than usual during pregnancy, after passing the first month or two, undoubtedly in part due to the support which the abdominal organs receive from the enlarging uterus. The labor also is usually easy with this type, as one would expect from the small amount of pelvic fat, the slender or small fibred pelvic muscles, and the slender pelvis with the loose pelvic joints. In the last month of pregnancy the sacral pain with frequent sciatica is easily understood by the form of the pelvic joints, and the quick relief from the pelvic joint strapping is not surprising. The possibility of increasing the diameters of the pelvis in this type and thereby assisting at the time of labor by simply manipu-

lating the sacrum should be realized, as well as the greater need of pelvic support, by swathe or strapping while the involution is going on. Also with this type, to maintain the higher position of the abdominal organs, the upright position should not be assumed until the abdominal wall has regained its proper tone and suitable corsets, to give low abdominal support, are fitted. It should be appreciated that conception with this type occurs easily and large families are common. With the heavy type childbearing is a more difficult matter, conception occurs less frequently, and the pregnancy is usually a time of much discomfort, with distressing back ache due partly to the relaxing of the broadly formed sacro-iliac joints and partly to the strain of the broadly formed lumbo-sacral joint, due to the changing poise. The labor is usually difficult, partly because of the general lack of flexibility of the pelvic girdle and the low back. It is with this type that back ache with referred leg pains often last for long after confinement because of the chronic joint strain.

With the normal human type the obstetrical condition is midway between these two types. It is neither as easy as with the slender nor as hard as with the heavy type.

It means that with the orthopedic conditions not only should the special joint or part be protected, but the type of the being as a whole should be studied and the function of the different parts assisted as much as possible. In the fitting of apparatus this is particularly important, and anything that interferes materially with the visceral function or with the proper development of the body as a whole should be most carefully avoided. This should be especially considered in some of the newer methods for the treatment of lateral curvature.

It means that, in the treatment of the common weak foot conditions, cure can hardly be expected unless the elements of faulty mechanics which have led to the foot strain are corrected. Of these, among the seemingly remote causes of strain, it should be remembered that the abnormal drag of the abdominal viscera will necessarily throw the body out of poise, so that the balance of the feet will be disturbed. It means that in the treatment of the common strains of the sacro-iliac joints that cure is not to be expected unless the abnormal forward inclination of the pelvis which has led to these strains is overcome. It means that in the treatment of the chronic joint diseases that the treatment of the local condition is only part of the problem. The joint symptoms are usually due to some systemic disturbance. To find the primal cause of the difficulty and see that that is corrected is naturally the most important function of the orthopedist.

It means, and this is apparently the most sobering phase of the subject, that as the result of the splendid work of our profession in preventive medicine, the slender type, which for-

merly because of its low resistance added so much to the mortality of infancy and childhood, is now being saved. It means also that with this type growth without proper guidance inevitably produces a still weaker physique, with drooped figure, narrow chest, etc., etc. These acquired characteristics added to the congenital form accentuate the congenital elements to such an extent that they are much more sure of being present in the following generation, and it becomes a mere matter of biology to see that such elements which represent physical instability will become more and more marked in the subsequent generations. This together with the fact that the slender type is the most prolific, makes evident that the stock from which the race is recruited will become steadily less strong. That this is actually taking place one has only to study any considerable group of school children of the present time to see how commonly the slender type is found. That this was not formerly the case is suggested, at least, by the study of the engravings of groups of individuals, such as were so commonly made from 50 to 100 years ago, in which the broad or round faced type is almost the only one shown. This is, of course, equally true at the present time in those countries in which modern medicine has exerted but little influence, and consequently the infant or child mortality is extremely high. The similarity in the form of the Oriental is apparently to be explained largely by this, as is true also of the form of the pure African. The slender type is not often seen among these races.

Since with the work of our profession and the general development of our civilization, the structure of the human family is being modified, it certainly behooves us to see that the modification is beneficial and not harmful. For this reason the great opportunity for our profession consists in not only saving the lives of those who are physically delicate, but in seeing that they are developed into stronger and more healthy individuals.

Similarly this is the great opportunity and responsibility for the educator. The slender child, if guided and trained rightly, becomes the agile, quick moving, quick thinking type of individual. To obtain such a development means most constant perseverance with the education and training of such a child, and this training should begin in the lowest grades of our school system, insistence being put always upon poise with its resulting efficiency. If the proper exercises are started in the lower grades and are increased in vigor and complexity as the child progresses, the children can be brought up to adult life with very different physique from that which is so commonly seen at the present day. One of the most serious phases of the educational aspect of the problem is that since this slender type is sensitively and nervously organized, with distinct nervous instability, intellec-

tual training must necessarily increase this instability, unless with the intellectual training the training of the body is insisted upon so that the proper physical support is given for the mental development. If education is approached in this manner it is a blessing, but if the intellectual aspect alone is held it must, in so far as this slender type is concerned, be harmful both to the individual and to the race.

One would certainly be a pessimist of the most profound type if he felt that the splendid work of our profession along preventive medical lines was a curse to the race by preserving the lives of the slender or delicate physical type, which Nature, in keeping with the law of the survival of the fittest, would have thrown off, or that the splendid work of the school and college is also harmful to the race by accentuating qualities of weakness; but such must be the fact, unless something else is added to the mere saving of the lives and to the common system of education as it exists today. If the physician and the teacher recognize these facts and apply the natural principles for the proper development of these individuals, the result must be inevitable—a stronger and finer race.

What higher incentive can there be for work than that which benefits the individual and at the same time by helping him gradually removes the weaker elements, which if perpetuated would surely lower the vitality of the race as a whole? The free will of choice with which man is endowed and upon which his moral development depends seems to find a similar responsibility in the development of a better and better creature along physical lines, and this development, as is true with the other, follows simple and understood laws. What greater incentive for one's best endeavor could a man desire than to become conscious of the greatness of this opportunity? In the moral choice man is given great responsibility and in the physical the responsibility is none the less great, unless the development of the human family is to be governed by the same law of survival of the fittest and natural selection which has governed the development of the lower forms of life. That man has for his future something better than these laws would make possible, everyone must feel who has thought at all beyond the needs of the day, and in the hope of stimulating thought and activities along these lines this contribution is presented.

Osler truly says, "collects a heavy toll of the unborn." The 113 given deaths represent his second group, and of these, 78 were under one year of age and succumbed probably to the direct lesions of the disease. "But the worm that never dieth and the fire that is never quenched express in simile," as he says, "the only too frequent history of syphilitic infection"—well chosen words we must admit, when we consider the third great group.

This includes the 231 who died of general paralysis of the insane; the 87 who died of tabes; one-half at least of the 372 labeled paralysis without specified cause; nearly all of the 56 recorded as softening of the brain; one-tenth at least of the 3496 who died of cerebral hemorrhage, nearly 500 of whom were between the ages of twenty and fifty; one-tenth perhaps of those 1979 under the heading of diseases of the arteries (atheroma, aneurysm, etc.), not to mention some of the 4610 organic diseases of the heart, a few of the 388 cirrhoses and other diseases of the liver, and a few of the 478 suicides. In round numbers, if we include still-births, we might place its mortality at 3000, or about one in every eighteen deaths, making its record of fatality fall behind only tuberculosis, pneumonia and cancer. Call this excessive if you will, and for the sake of conservatism divide the mortality by two. Yet it still remains high enough to attract the attention of the doubter.

My purpose in presenting these figures is simply to forestall the criticism that one interested in this disease can see nothing else, and also to give some food for thought to those who rather boastfully say that they never come across a case of syphilis. But my special topic tonight is a consideration of this disease in its relation to lung disease, a subject that has not received at the hands of American writers the attention commensurate with its importance. Whether or not syphilis of the lung is as infrequent as some believe is a debatable question. There are those who say that it is not of such rare occurrence and that it is often overlooked because it is difficult to distinguish between this lesion of the lung and pulmonary tuberculosis, not only at the bedside, but in the pathological laboratory. Stengel³ says that there is no disease in which it is more necessary to carefully weigh the pathological findings with the clinical history before giving an opinion. The finding of the tubercle bacilli is the only absolutely certain point of difference and even this does not preclude the possibility of associated syphilis. Pulmonary tuberculosis is so common and syphilis thought to be so rare that it is not at all improbable that some of these cases slip by with a diagnosis of tuberculosis. Moreover, many cases of supposed phthisis give such a typical history and show such characteristic signs of the disease that it does not seem necessary to examine the sputum. Even if the bacilli are not found after several examinations, no change in the diagnosis is made.

SYPHILIS AND LUNG DISEASE.*

BY ANDREW F. DOWNING, M.D., CAMBRIDGE, MASS.

IN the Schorstein Lecture¹ Osler, with characteristic skill, paints a picture of the harvest reaped by syphilis, and sets down indisputably in cold figures the high position it occupies in the "hierarchy of the infections." For the year 1907, he places its mortality in England and Wales at between six and seven thousand, or about one in eighty deaths, and this does not take into consideration the unestimated and very large number of still births. In short, he reckons syphilis as sixth in the list of diseases due to specific germs, although in the registrar-general's report for 1907, only 1658 deaths are charged to the spirochete.

Following Osler's line of reasoning, let us turn to the vital statistics of Massachusetts for the year 1912 and see if we can get some idea of the prevalence of syphilis in this Commonwealth. If we expect the figures to show it as a killing disease, we shall be disappointed, for the spirochete is held responsible for only 113 deaths.² Remembering, however, that syphilis can kill in three ways and at three different periods, we can readily see that these figures by no means tell the tale. Of the 3188 still births, half at least may be credited to the spirochete, which, as

* Read before the Charlestown Medical Society, Feb. 15, 1915.

The same line of argument is used in the autopsy room. The condition is so much more likely to be tubercular than luetic that it is almost always placed in the former class unless syphilitic lesions of a pronounced character are found in other organs.⁴

In reviewing the literature before the discovery of the tubercle bacillus, we find syphilitic phthisis mentioned by many authors. Morgagni⁵ makes note of a phthisis, a *lue venerea*, and of its cure by anti-syphilitic treatment. Virchow⁶ insisted that contributions on the subject by Graves, Stokes, Laennec and Yvaren were of little worth since they lacked anatomical confirmation. In 1862, Virchow himself had a case which clinically and later at autopsy showed lung syphilis. The costal pleura was thickly seeded with yellowish miliary and larger flattened areas of thickening, most of which were grouped about a projecting flattened scar-like area with radiating margins. In the lungs were multiple nodules, the largest from the size of a pea to the size of a walnut, with softened centres often forming bronchiectatic cavities. These pleural and pulmonary lesions in association with typical constitutional syphilis, served to recall to Virchow a few cases of similar lesions in congenitally syphilitic infants. In these cases nodules were found in the pleura and in the lung substance around the bronchi. The so-called white hepatization of the still-born first described by Virchow in 1847, was shown by Hecker in 1854 to be due to syphilis.

In acquired syphilis there is a second or interstitial form as distinguished from the one with multiple gummata described above. In this form, met with post mortem in old syphilitic subjects, the fibrous tissue is seen most commonly and abundantly at the hilus of the lung, whence it may extend as dense bands into the interior along the air tubes and blood vessels. It may be quite general and lead to extensive pulmonary fibrosis and shrinkage, or it may occur in scattered areas. The disease is usually unilateral and there are commonly also dense, firm adhesions in the pleural cavity. This interstitial hyperplasia displays no characteristics that serve to distinguish it from fibrosis due to tuberculosis, unless it be its tendency to be confined to but one lung, and to occupy the middle parts of the organ. It is this difficulty probably in distinguishing between the two that makes our autopsy records show so few cases of specific lung disease. This will, perhaps, explain why Osler observed only twelve cases in twenty-eight hundred autopsies at Johns Hopkins, and why not a single case was observed in three thousand autopsies at the Massachusetts General Hospital.

It is to clinical evidence then that we must turn, for since syphilis of the lung is a curable condition, it is not strange that we find so little evidence of it at autopsy. Fournier lectured on it in 1876, and in 1877 Porter read the first paper on the subject in this country. Satter-

waithe, in 1891, in the BOSTON MEDICAL AND SURGICAL JOURNAL, reported some cases and expressed the opinion that lung syphilis was greatly underestimated and even unknown to many syphilographers. In 1891⁷ also, Councilman reported two cases of lung syphilis demonstrated at autopsy in which the diagnosis had not been definitely made before death. In this article, he says that he has found it to be comparatively rare, although he adds that it is difficult to see why this should be so. In England, France, and occasionally in this country many cases of clinical luetic lung disease have been reported. In most instances they were clinically identical with consumption in its various stages, were at first diagnosed and treated as such, but finally, on account of repeated failures to find the bacilli, were recognized and treated as syphilis with happy results. For example, Dr. L. Brown in *Johns Hopkins Bulletin*, April, 1914, reports a number of such cases under the heading of "Some Errors in the Diagnosis of Pulmonary Tuberculosis." Brown of St. Louis reported several cases May, 1914.⁸ Burnham⁹ of Boston reported the case of a woman who was admitted to one of our state sanatoria with the diagnosis of advanced phthisis. After a month or so, she left the sanatorium against advice, was afterwards labeled second and third stage tuberculosis at various clinics, and yet all the while the sputum was negative. Burnham, suspecting her true condition, had the blood examined with a positive result, and under specific treatment her recovery was rapid.

Three years ago I saw a young man twenty-six years of age, with a history of a hard sore about a year previous. He was twenty-five pounds under weight, was pale and had a mouth full of sores. He had a severe cough and marked dyspnea. His story was that he was never able to stand much treatment with mercury, but had progressed fairly well until four months before I saw him, when he developed a hard cough. His appetite became very poor, he began to lose weight, and his stomach could not stand the mercury which he had been taking by mouth. Discouraged, he stopped all treatment and began to drink. Mucous patches appeared in his mouth and around his anus; he had bloody sputum and night sweats. Lung examination showed both tops filled with sibilant râles and a percussion note that was none too good. At the time I thought that I was dealing with a case of phthisis complicated with syphilis and gave a rather discouraging prognosis to his friends. His sputum was not examined, as on the following day I gave him an intravenous injection of salvarsan which caused an immediate change for the better. A month later I hardly knew him, so rapid had been his gain in weight. Not long ago I heard from him from Philadelphia, where he now lives. He feels perfectly well and is still taking specific treatment at intervals. What he was suffering from was probably a

syphilitic tracheo-bronchitis which, had it gone untreated, would, I believe, have soon developed into a rapidly advancing case of pulmonary tuberculosis. It is interesting to note that in this case the patient had an idiosyncrasy to mercury, and the rapidity with which he cleared was a tribute to the efficacy of salvarsan.

Some time ago, in my work as an examiner, I saw a man with a solid left base, evidently an old fibroid condition. He was also rather wheezy with a chronic bronchitis. Although pale, he looked fairly well and apparently had not lost any weight. Over his left scapula was a small, suspicious-looking serpiginous lesion. He denied syphilis and was very indignant when I told him that I would have to reject him. Of course I was unable to follow up this case, but I feel that I am not unreasonable when I say that his was probably a clinical case of lung syphilis.

Not long ago I was consulted by a stout, healthy-looking man of fifty, on whom a diagnosis of second stage phthisis had been made. He had a cough, slight loss of weight and a suspicious condition at the tops of both lungs. His cough was one of those irritating ones, out of all proportion to the physical signs. In reply to my routine question about syphilis he promptly replied that he had what he termed "syph" twenty-five years ago, but said that he had taken treatment for five years and supposed that he was cured. I was interested enough to take some blood for a Wassermann test, which proved to be strongly positive. He was given three intravenous injections of neosalvarsan and later put through a course of mercury intramuscularly. Then he was given mixed treatment. After four months it is interesting to note that he still went strongly positive. Clinically the result was all that could be hoped for. His lung condition cleared and he felt better than he ever did before. Here, again, I believe that I was dealing with a case of clinical syphilitic phthisis that might have found its way to a tuberculosis sanatorium.

Osler reports the case of a man of twenty-seven admitted in April, 1902, who for years had cough and bloody expectoration and who died of severe hemoptysis. Bacilli were never found in the sputum. There were extensive caseous gunmata throughout both lungs, with much fibrous thickening, and in the lower lobe of the right lung a cavity three by five centimeters in diameter, on the wall of which a branch of the pulmonary artery was eroded.

These are only a few of a number of cases either clinical or pathological, that might be mentioned. The point that I wish to emphasize is that their occurrence is an established fact that cannot be lightly set aside.

Fully as much neglected as luetic phthisis is a more frequent condition, the association of syphilis as a general disease and pulmonary tuberculosis. Occasionally we read of striking improvement in pulmonary tuberculosis by the intra-

muscular administration of the succinimide of mercury. It seems reasonable to suppose that these are cases of phthisis complicated with syphilis. We hear very little of lues as a predisposing factor in pulmonary tuberculosis. Fowler and Godlee in their book on Diseases of the Lungs (1898) put due emphasis on the fact that syphilis, by lowering the resistance, may predispose to consumption. They state that it has been shown by Hocksinger (1894) that the virus of syphilis and tuberculosis may be jointly transmitted from parent to offspring. They cite his cases of three infants suffering from congenital syphilis and presenting symptoms of lung infiltration in whom the pulmonary disease was found post mortem to be due to tuberculosis and not to syphilis. The bacilli were found in the lungs in all three cases. Fournier remarks, "I have already seen a number of patients become tuberculous in whom syphilis had powerfully exerted its depressing influence." "Again," he says, "from my own personal experience, as well as from what has been said on this subject by the highest authorities, I do not hesitate to inscribe syphilis in the etiological chapter of pulmonary tuberculosis."

Sergent¹¹ of Paris, who has made a special study of the association of these two diseases, which he has embodied in a monograph on the subject, believes that syphilis is a common predisposing cause of tuberculosis, and that it prepares a soil (terrain) favorable to the growth of the tubercle bacilli, and that this special soil is transmissible to the descendants. The active consumptive, he says, receives a mortal blow when he contracts syphilis. With the inactive case the outlook is brighter. When a syphilitic becomes tuberculous, the prognosis varies according as to when he contracts his phthisis. If it is in the tertiary stage it is always inactive or benign. He makes the interesting suggestion that syphilis may be at the bottom of inactive tuberculosis in the form of emphysema. He concludes his study of these associated conditions by stating that he cannot always agree with the old idea that lues and consumption combined constitute the most formidable of diseases. We must consider in each case the soil, the malignity of the diathesis and the response to proper treatment before giving up the case as hopeless.

Guerin¹² of Bordeaux, who has also labored in this particular field, warns us to look always for tuberculosis in the presence of syphilis. Gouget¹³ of Paris reports a case of a woman with cutaneous specific lesions and definite signs in the right lung, with bacilli in the sputum. Under mercury her skin lesions disappeared and the lung process became inactive. Like Sergent, he feels that syphilis is a favorite soil for the development of tuberculosis, and in the case of the consumptive who became syphilitic, he lays down the following rules: If the lung is active the process rapidly advances and death soon intervenes. If it is inactive the-

chances are better. In the case of the luetic who becomes tubercular, he, too, says that if the tuberculosis is acquired in the secondary stage it advances rapidly, and our prognosis should always be grave. In the tertiary stage, the patient is predisposed to a fibrous evolution of his tubercular process, thanks perhaps to his arterial hypertension. The serious cases belong to secondary syphilis and active tuberculosis.

Some observations on this subject by Mr. D'Arcy Power¹⁴ are also interesting. Children and adults with the taint of inherited syphilis often show signs of tubercular joint disease in the form of a gummatous synovitis, which does not improve beyond a certain point under anti-syphilitic remedies. In young adults born of specific parents an attack of pneumonia or other infectious disease may be followed by signs of syphilitic inflammation. The syphilitic lesions thus manifested may become tubercular and the patient die of tuberculosis. Old persons who have acquired syphilis many years previous show a tendency to be attacked by senile tuberculosis.

Enough has been said to show the magnitude and the importance of this subject. It is a question that the tuberculous expert cannot disregard. No great public movement in preventive medicine has fallen into such a rut on the scientific side as the fight against consumption. In a spirit of suggestion, therefore, rather than criticism, I recommend to the leaders in this work a field of investigation that is worthy of a live effort.

RABIES IN CHINA.

BY ALFRED C. REED, M.D.,

The Yale Hospital, Changsha, China.

RABIES as a distinct and commonly recognized disease entity, has a history in China running back into the dim annals of the nation's youth. Chinese nosological writings are characteristically indefinite, and because the so-called scientific method is not employed, their conclusions are often peculiarly naive and devoid of reason.

In spite of this fundamental defect, however, the Chinese observation of natural phenomena is often surprisingly accurate and circumstantial even though their deductions therefrom may be far from the fact. Thus in the case of rabies, the absence of the scientific method has prevented their following up the data accepted as fact, the fruit of their own observation.

From remote times rabies in man has been known in China and has been connected with the same disease in dogs. Apparently other animals, domestic or wild, have not been considered subject to the disease, but in dogs it has been described very definitely. It is called the "mad dog disease" or "the serious disease of lower animals." Here, as in other matters, there is undoubtedly a variety of belief in different parts of China, but the data presented may be taken as typical and accurate for Changsha. Strangely enough, no word corresponding to "hydrophobia" is known, nor has any reference been found of observation of aversion to water on the part of rabid dogs or men.

In the time of Chum Tzu, who was a contemporary of Confucius, it is recorded that a mad dog attacked the people of Sung, this being a dynastic name applied at that time to the Chinese Empire. The people were terrified and banded together to kill the dog, but it ran away and made its escape. This shows, so the Chinese say, that the mad dog was as greatly feared at that early time as it is today. Rabies in human beings is considered to be very difficult to cure and often incurable. Men more frequently contract it than women because men more often attack mad dogs and are thus exposed to infection. In killing or attacking a mad dog it is held that care must be exercised because the poison may be transmitted from the dog to a stick by the saliva, and from the stick to man by contact. The same is noted with reference to clothing and it is held by some that a man may become infected merely by having his stick or his clothes bitten by a mad dog. The infectivity of the saliva is clearly recognized. For this reason it is recommended that a certain kind of stick alone be used, a variety of black bamboo. This is semi-traditional but has basis in reason in that such a stick is so smooth and hard that a dog cannot bite it and the saliva is not retained.

The diagnosis of rabies in man or dog is made by the Chinese practitioner on the following points. By striking a brass gong or pan sharply before the suspect, extreme fear is produced and sometimes convulsions. The same follows vigorous fanning with a palm fan. Another diagnostic method in man is to feed some yellow or black beans. If the man finds the taste sweet and pleasant and enjoys the eating, it is an evident sign of madness, but if the taste seems bitter and there is no pleasure in the eating, the poison of madness is not present. Again, madness may be recognized in man by rubbing his chest with a cash. If red streaks appear, it is a

positive sign. The growth of red hair is another sign.

The essential cause of the disease is laid to a disturbed relation of the gases or atmosphere of the body, resulting in a poisoning of the blood. The incubation or latent period of the disease is observed to be quite variable and often delayed. The poison may remain inactive in a man's body for seven days after being bitten or for seven times seven days, or even for one hundred days, before hydrophobia develops. The length of the incubation period depends on the strength and health of the man and the virulence of the poison. Some say that a man with rabies cannot live more than one hundred days, but that if he hears gun-firing, firecrackers or other loud, harsh noises, he may go into convulsions and die in great pain at once. With the development of the disease the patient experiences a severe cutting pain through the heart and is apt to lose consciousness. His strength is greatly increased, and in his fury he rages, tears, bites and howls just as does the mad dog. The urine and stools are supposed to be suppressed, and this is accompanied by severe pain in the penis, anus and around the waist. The victim tears off his clothing, scratches in the earth, bites everything near him, including his own hands, and in a few hours dies. The sufferings are described as fearful.

Various etiological factors are designated to account for madness in dogs. The following have been especially noted:—

1. In the winter venomous snakes and poisonous reptiles hibernate in caves and holes in the ground, for fear of the cold weather. While the surface of the earth is cold there is still warmth underneath. With the coming of spring these reptiles gradually become reanimated and crawl out of their places of concealment, into the air. During their long sleep, poisonous gases and noxious vapors have accumulated in them, and when they first begin to breathe again these are given off at the mouth of the cave or hole. Dogs smell at these holes and inhale the poisonous vapors, which go through the lungs to the brain and cause madness. The disease in the dog is thus located in the brain.

2. Madness is transmitted from one dog to other dogs, by bites, through the medium of infected saliva.

3. It is said that dogs become mad after eating toads from ponds or pools in the spring of the year.

4. Dogs become mad also from licking up the exuding sap from trees and bushes cut off in the spring when the sap is beginning to flow.

5. When, from some such cause as mentioned, dogs get the poison of rabies in their system, the virus may still not be strong enough to cause madness, but the progeny of such a dog may by inheritance suffer from rabies.

6. In the putrefying bodies of dogs dead from rabies there is engendered an infective agent, microbic or vaporous, which may transmit the disease to other dogs smelling the carcass.

7. Mad dogs discharge on the ground as they run, a strong and venomous fluid, which transmits the disease to other dogs smelling it or licking it up.

8. One interesting theory is that from eating too hot food a dog may develop a great internal heat which causes madness. If by any means this internal heat can be alleviated, the disease is cured.

9. There is an ancient tradition in Hunan that rabies in man is due to the virus from the bite of a mad dog. This virus in the course of 21 days in a man or 14 days in a woman, engenders in the stomach a small puppy which rapidly grows, and by its biting, scratching and growling is responsible for the symptoms observed in the victim.

Most of these causes of madness in dogs are only operative in the spring of the year. Therefore it is considered that dogs should receive special care and protection in the spring. Mad dogs are often difficult to recognize, but can usually be recognized by the fact that they hang down their ears, head, and tail, that they have red eyes, run very fast and far, and that they have "hard strong necks." Then, too, as stated above, they are in terror before a sounding brass gong or if fanned with a palm fan. If the poison penetrates to the heart, it will affect the tongue, which hangs out. If it reaches the liver, vision is lost. In the stomach it results in abundant and poisonous saliva. In the lungs it causes loss of voice. In the lower part of the body it makes the tail hang down between the legs. In man rabies is said to cause the growth of red hair, which must be pulled out by the root if a cure is to be effected.

Among the Chinese physicians of the native school many remedies are in vogue, many of them hoary with the use and belief of centuries. One method of treatment is to wash the dog-bite with rice water, then to scarify with a silver prong until all the poisoned blood has escaped, then to apply a wet poultice of chewed almonds, which draws out and neutralizes the poison. Other remedies in good repute are a preparation of ginseng, which is considered an antidote, and a dose made by pulverizing certain small insects, like lice. By some of the native doctors this latter is held to be almost a specific.

One old style Chinese practitioner, after describing the symptoms of rabies in man, stated that not one case in a hundred recovered, even with the ordinary modes of treatment. He then naively remarked, "But if they will take my medicine they will get well immediately." His specific treatment was the following: Immediately after being bitten by a rabid dog the

victim is taken away to a secret room in the interior of a house where wind, noise and bright light are excluded. His entire body is washed with cold tea. The wound is bound up with a chewed almond poultice made with a vegetable juice called 'gin tsai.' This poultice is changed once in seven days. After 49 days a white surface appears on the wound. Then a preparation of wild mint supersedes the almonds. From the first a dose of medicine is given daily for seven days consisting of the following: angelica root, 2 oz.; liquorice, 2 oz.; peppermint, 2 oz.; orange peel, 2 oz.; ginger, 5 oz.; purple bamboo root, 10 oz.; sarsaparilla, 6 oz.; ginseng, 3 oz.; an unidentified plant from Ningpo, related to *atractylis ovata*, 2 oz.; *pinella tuberifera*, 2 oz.; a plant from Szechuen, not classified, 2 oz.; *ligusticum acutilobum* (probably), 1 oz.; root of *rehmannia glutinosa*, 1 oz. This is boiled together and the liquor drunk at one draught.

After the first seven days the bean chewing test is employed and is repeated at intervals of one week. When the test becomes negative a cure is considered established. The old native doctor reports having seen three men bitten by a mad dog and one of them saved by this treatment. After being cured by this method the patient must refrain from pork, fish and wine for one year, and must eat no dog meat or red beans as long as he lives. Otherwise the disease is sure to recur. During the treatment and up to one hundred days after the dog bite, the patient must eat no salty or sour thing. The principle of this treatment is two-fold. First it is supposed to neutralize the poison and draw it from the wound, and second it is supposed to decrease the internal temperature.

Chinese prescriptions are characterized by great bulk, large variety of drugs and unpleasant taste, and its effectiveness is often measured by these standards. The following is a fair sample in general and it illustrates the formula administered in rabies by a Chinese physician of wide repute in Changsha.

Bamboo root, an indefinite quantity.

Raw hypericum, 1 oz.

Ginger root, 3/10 oz.

Liquorice, 3/10 oz.

Angelica root, 3/10 oz.

Root of *platycodon grandiflorum*, 2/10 oz. (Used as a common cough remedy).

Red gentian, 3/10 oz. (a general tonic).

Root similar to ginseng, 3/10 oz.

Rind of *citrus aurantium*, 3/10 oz.

Pachyma cocos, 3/10 oz (a false tuber growing fungus-like on the roots of fir trees. Commonly called "China root").

A red colored root from Szechuen Province, 2/10 oz. (used in liver complaints and as blood purifier).

These are boiled together in a large vessel of water to a thick fluid, and the decoction is to be taken at one dose before it cools.

It is interesting to compare these ideas which have been held for centuries by the Chinese with certain conceptions current until quite recent times in Europe and America. According to Stimson¹ (*Hyg. Lab. Bull.* 65, 1910), the western history of rabies dates back to the time of Aristotle and Democritus in the fourth and fifth centuries B.C. respectively. Celsus in the first century A.D. gave the first detailed description of the disease, which was amplified by Caelius Aurelius and Celsus in the second century. Without much change these early conceptions came down through the middle ages, until the nineteenth century, when inoculation experiments and scientific investigation of rabies culminated in the epochal researches and productions of Pasteur.

A few facts not ordinarily known are yet matters of old observation and record and justify repetition. Short-haired dogs more frequently become rabid than do long-haired dogs, because the saliva is rubbed off on the long hair. Young dogs are susceptible as well as old ones. The saliva of a rabid dog may be virulent before the appearance of symptoms. Fear of water is infrequent in rabid animals. It is not mentioned in Chinese annals. Mad dogs may be playful at first and do not always froth at the mouth or carry the tail between the legs.

Avicenna taught that the cause of rabies consisted of small likenesses of dogs which were passed in the urine of the victim of rabies after having taken cantharides. These were really blood clots. Their passage was supposed to result in cure. Frederick the Great promulgated a decree providing for the removal from dogs' tongues of the so-called "mad worm," later found to be a normal cartilage of the tongue. This was done to prevent the animals from contracting rabies. To diagnose rabies at one time it was the custom to apply the bared breast of a living fowl to the dog-bite. The death of the fowl proved the poison of rabies present. The mad stones, which are said by Stimson to be still used in certain parts of the United States, are quoted by him to consist of tri-calcium phosphate, obtained as calculi from the gastro-intestinal tract of various animals. They are said to adhere to such poisoned wounds as dog or snake bites and to draw out the poison. Evidence of this is to be found in their discoloration when later boiled in milk. Not even yet has the belief in the spontaneous origin of rabies been entirely abandoned, although modern investigation proves conclusively that the disease is essentially an infective process and that each case depends on inoculation with the specific virus.

There is a parallelism between the observations and deductions of the Chinese and of occidental peoples. While the scientific descriptions and conclusions in the west have been far more accurate and detailed than any in China, never

¹The facts noted in regard to the history of rabies in western countries are taken from Stimson's excellent monograph.

whether the subject be scientific, political, or the popular beliefs of the Chinese compare very favorably with those of western races. The Chinese does not use our system of logic and sequence in his reasoning. But the essential point is that he has a system, even though it be radically different from anything known in the west, and to the best of his ability he consistently follows this system in his reasoning, or philosophical. His standard of judgment does not lie in efficiency or results, but in the test of antiquity. To be old is to be good. Whether measured by his own or by the western standard, the native Chinese ideas of rabies suffer little in comparison with the ideas current in the west until a generation ago or less.

TUBERCULOUS INFECTION AS A DISEASE ENTITY.*

BY GEORGE THOMAS PALMER, M.D., SPRINGFIELD, ILL.

President of the Illinois State Association for the Prevention of Tuberculosis; Director of the Springfield Open Air Colony.

WITH the development of a relatively new art,—the early diagnosis of tuberculosis,—we find ourselves in a place where we must readjust our attitude toward the general tuberculosis problem. While we have quite readily accepted the belief that the majority of persons have a tuberculous infection at one time of life or another, and while we have recognized that a large number of individuals carry a dormant infection from childhood, we have been very slow to appreciate what these facts must mean in our general attitude toward the disease.

The more recent trend of opinion develops several other facts radically altering the tuberculosis problem. With the acceptance of the doctrine that tuberculosis is largely a childhood infection, we have come to believe that the disease is not as infectious to healthy adults as we had once believed. Further, those who have engaged extensively in the clinical study of the disease have come to feel that tuberculous infection manifests itself very frequently in other forms than those formerly recognized as tuberculosis.

It is untenable that an infection as common as this should give but one of two results; on the one hand, a serious and often deadly disease; on the other, no recognizable disease at all. It is more reasonable to assume that there is a broad borderland between health and active tuberculosis,—that tuberculous infection may cause numerous forms of illness, varying all the way from simple "poor health" to actual physical ailment.

* Presented before the Chicago Medical Society on April 28, 1915.

That such is the case is borne out by our newer conception of tuberculous infection as the causal factor in many cases of so-called neurasthenia and in those diagnosed as typhoid fever (especially of the ambulatory type and without rose spots), exophthalmic goitre (with elevated temperature), "nervous dyspepsia," and various digestive disturbances, malaria (without demonstration of the plasmodium), and so on.

Our present ability to diagnose tuberculous infection in the absence of clinical evidence of disease, or with signs and symptoms previously ignored or regarded as insignificant, renders it necessary for us to alter our methods in advising and treating our patients, and compels us to adopt measures more suitable to the "new disease," which this earlier diagnosis has developed.

Formerly, a clinical diagnosis of tuberculosis suggested one of three courses: (a) sanatorium treatment, (b) out-of-door treatment at home, or (c) ambulatory treatment with tuberculin or other medicinal agents. This program, with no alternative, implies that in all cases of demonstrable tuberculous infection we are justified in disrupting the individual's business and social life and in making him an invalid. This is one of the beliefs which, in the light of our present knowledge, is open to serious question.

Some one has suggested that tuberculosis is a disease of nutrition in which the tubercle bacillus is an incidental factor. While we are not quite ready to accept this very sweeping assertion, we must recognize that thousands of persons are carrying inactive tubercle bacilli constantly with them and that their safety depends upon their maintenance of good bodily health. The development of active tuberculosis among previously healthy persons, after debilitating disease or physical or mental strain, and without known exposure to tuberculous infection, is too commonly noted by physicians to require comment.

Hence it is reasonable to assume that the course to be pursued in those cases in which tuberculous infection is demonstrated without diagnosis of tuberculous disease, is that of building up the general health and thereby increasing the bodily resistance.

Such, in fact, is the basis of our present hygienic treatment of tuberculous disease and such is the plan of sanatorium treatment. Out-of-door sleeping, plenty of nourishing food, rest and carefully supervised life, are merely our means of aiding the individual to fight his own battle against the bacilli. Where this method of treatment has gone beyond the limits of rational living,—as in undue hardships or exposure and in forced feeding,—it has failed.

For the patient with any degree of disease activity—which means the patient with clinical tuberculosis,—sanatorium treatment, with its prolonged rest and rigid supervision, must be insisted upon. For the individual whose infection is demonstrated, but found to be wholly

inactive, I am impressed that regulation of life need not be pushed to a point incompatible with ordinarily useful existence.

For example, we find many patients without evidence of disease who give decided reaction to tuberculin administered intracutaneously or subcutaneously.* This patient may complain of weariness. He may have had slight loss of weight or finicky appetite. He has no elevation of temperature and no digestive disturbance. Physical examination may be entirely negative. To the more careful observer it may reveal a retracted apex or some old lesion apparently quite inactive.

This individual doubtless has tuberculous infection. To conclude that he is a consumptive and likely to prompt breakdown is the height of folly. To entirely disrupt his life and relegate him to a sanatorium is unjustifiable. He does require the readjustment of his methods of life, however, and in this his physician should be his constant guide and advisor. He must not be branded as "tuberculous," with all of the present blighting significance of that term.

The French have classified tuberculosis in four groups: (1) That which is never recognized or suspected,—in which the patient never knows that he is in any sense unwell. (2) That which is cured by a vacation without recognition of its true nature. (3) The tuberculosis which we now recognize clinically and which may be cured by our present means. (4) The massive, acute tuberculosis in which all treatment is futile. And it must be recognized that most of our cases come in the first two groups: that they are not recognized during life as tuberculosis.

There are scores of persons who come to the physician who are found to have tuberculous infection and who, on careful examination, are found to have slight evidence of physical disturbance or ill health, who should be regarded as tuberculous in a modified sense,—“pre-tuberculous,” perhaps,—who should begin their treatment with a sane vacation and who should complete it by intelligent supervision while they pursue their normal lives.

As to whether or not tuberculin is indicated in these cases is a matter for the decision of physicians who are experienced in its use. Certainly tuberculin should be given rarely if at all by the man whose many and varied duties in general practice prevent his becoming thoroughly conversant with this valuable but dangerous agent.

Whatever the method of treatment, the recognition of “tuberculous infection” as a disease condition meriting curative effort on the part of the physician, will not only do more than any other factor in checking the shocking morbidity and mortality of this disease; but it will restore to health thousands of those now suffering from

vague and indefinite disease and will serve to decrease the countless legions of those who now constitute the army of “poor health.”

It is hardly necessary to add that the success of this line of action will depend, to a large extent, upon the skill of the physician as a general diagnostician. Even though the patient may have an unquestioned tuberculous infection, it is not rational to attribute his vague ill health to this cause alone unless we have eliminated or carefully weighed all other conditions to which the ill health may be wholly or partly attributable. But, in my opinion, after all of the other causes have been disposed of, there will be found scores of persons in whom a partly latent tuberculosis is the only demonstrable cause of physical deficiency.

It is not necessary to enumerate the groups of persons in which these cases will be found. Neurologists already recognize the importance of closed tuberculous lesions as causal factors in nervous disorders. Thousands of persons, after prolonged stomach and intestinal disorders, arrive at the final conclusion of their tuberculous condition; other thousands doubtless never reach this definite conclusion. The waiting rooms of laryngologists and rhinologists will offer a fertile field in our search for subjects. And yet the greater number will probably come from the ranks of those in “poor health,”—the never-sick-never-wells,—those who are forever physically inefficient and below par,—those who are “naturally thin” with poor digestions, poor appetites, unstrung nerves and feeble endurance. If our applicants for “spring tonics,” and consumers of patent medicines were subjected to competent examination, the results would be striking. * * *

Another point which, in my opinion, will be an exceedingly important one during the next few years, is the relationship of tuberculous infection to life insurance risk. In the past, insurance companies have rejected those who have family history showing tuberculosis and, even to-day, they are viewing the disease with the utmost suspicion. There are few companies, if any, which would accept an applicant who stated frankly that he had a tuberculous infection, and yet these same companies are annually accepting not only those who have infection, but those who have demonstrable tuberculous disease.

This is due to the fact, of course, that tuberculosis, tardily diagnosed, is and always has been and always will be an extremely deadly disease and, further, that no company is requiring as careful scrutiny on the part of its examiners as would be required to detect this very common disease in its incipency.

The interesting question arises, however, as to what attitude insurance companies can take when their examiners perfect themselves in diagnosis and begin to report scores of otherwise healthy applicants who have unquestioned, but presumably inactive, tuberculous infections. If

* It seems hardly necessary to state that the von Pirquet test is absolutely useless in the diagnosis of tuberculous infection in adults.

they assume their present attitude toward the disease, the companies having the most thorough and competent examiners will have rejections which will hopelessly discourage their agents and insurance selling forces.

I do not mean to say that those applicants now diagnosed as tuberculous should be accepted as risks. On the contrary, the number of deaths from tuberculosis among recently insured persons is inexcusably large. It unquestionably indicates that active tuberculosis is frequently overlooked by examiners.

At the present time, however, early diagnosis of tuberculosis is developing rapidly. Not only are certain individuals who devote themselves to the subject, acquiring a high degree of proficiency; but the better class of physicians are appreciating the former neglect of this important branch of their work and are schooling themselves accordingly. Hence, it will not be long before insurance companies will have to radically change their attitude toward the disease or they will be compelled to reject hundreds of persons with tuberculous infection who are in every sense quite as good risks as the average of those now accepted.

The recognition of tuberculous infection as distinct from tuberculous disease will do much toward ridding this common disease of its present terrors and will go far toward solving the entire tuberculosis problem. The failure of medical men to see the various stages of tuberculosis in their proper proportions and their reluctance to present inevitable and indisputable fact to the patient, is largely responsible for the blind and unreasoning dread of the word "tuberculosis" among the people.

Not until the medical profession sees the disease in a different light will the patient receive his diagnosis sanely nor will he receive it early enough to save him from prolonged illness or unnecessary death.

Pottenger is responsible for the assertion that there is a time in which every case of tuberculosis is curable. This is not, however, after it can be demonstrated by ordinary means of physical examination even at the hands of the most talented of diagnosticians. And even in the massive, acute form of the disease, there is doubtless a period in which cure could be brought about. That time, however, may have been twenty years ago, when it could not have been recognized as a disease at all; but merely as an infection.

PROGRAM AND DIRECTIONS FOR THE MENTAL EXAMINATION OF ASOCIAL, PSYCHOPATHIC AND DOUBTFUL SUBJECTS.

BY ROSE S. HARDWICK, BOSTON.

Instructor in Education, Boston School of Physical Education; formerly Assistant in Psychology, Psychopathic Hospital, Boston.

(Continued from page 865.)

ROUTINE PROGRAMS.

The following are minimum programs. One of them should seldom occupy less than an hour or more than an hour and a half. The data so obtained may be supplemented by means of additional tests selected from Table 2 on page 60, in accordance with the nature of the individual problem.

The Yerkes-Bridges Point Scale is made the basis of the examination, except for illiterates and non-English speaking subjects, when it is replaced by the Knox Scale. It is true that all save one (No. 18) of the Point Scale tests can be given to illiterates, but such subjects are at a disadvantage with many of the other tests, partly through inferior training, and partly through their diffidence in the presence of anything that is to them suggestive of the school-room.

For the present it is desirable to secure the Binet rating whenever possible for the purpose of comparison, especially as this can be done at the cost of so little additional time.

Most cases can be classified, conveniently for examination purposes, as precautionary, mental cases, social cases, suspected psychoses, illiterates and non-English speaking* subjects. The routine programs subjoined are arranged under these heads. The sense in which each of these phrases is used will be discussed in the following section. This classification is open to criticism on logical grounds but it is believed that it will be found convenient in practice.

I. PRECAUTIONARY CASES.

1. Y, in full.
2. B, to obtain rating.
3. One of the following tests:
(3-9 years) H I,
(From 9 years) H XXIII.

II. MENTAL CASES.

1. Y, in full.
2. B, to obtain rating.
3. Two of the following tests, including, if possible, H XXIII:

* In this discussion, "non-English speaking" is used of the individual subject. This differs from the usage in the publications under No. 11 of the references on page 63 (given also under "Working References," page 6), where "non-English" and "non-English speaking" appear as abbreviated forms of the expression, "children of non-English speaking parents."

- (4-5 years) Seguin's form-board,
- (4-9 years) H I,
- (5-8 years) H II,
- (From 8 years) H III,
- (From 9 years) H XXIII,
- (From 10 years) H IV,
- (From 12 years) H V.

4. As many of the following tests as are applicable:

- (From 7 years) H VIII,
- (From 7 years) H XIII,
- (From 9 years) H XII.

5. (Adults) prose completion, and labyrinths.

III. SOCIAL CASES.

1. Y, in full.
 2. B, to obtain rating.
 3. One of the following tests:
(3-4 years) Seguin's form-board,
(4-9 years) H I,
(From 9 years) H XXIII.
 4. (a) Unstable individuals:
(From 6 years) H VI,
(From 7 years) H XIII,
(From 12 years) H XVI,
(From 14 years) labyrinths.
(b) Court cases and delinquents:
(From 6 years) H VI,
(From 9 years) H XXI and XXII.
(From 13 years) ethical discrimination,
(From 14 years) labyrinths, and K adult 7.
 - (c) Economic cases:
(From 7 years) H VIII and XIII,
(From 12 years) H XVI.
- Also, two of the following tests:
(From 8 years) H III,
(From 10 years) H IV,
(From 12 years) H V.

IV. SUSPECTED PSYCHOSES.

A. English speaking subjects:—

1. Y, in full.
2. B, to obtain rating.
3. One of the following tests:
(4-9 years) H I,
(From 9 years) H XXIII.
4. One of the following tests:
(From 8 years) H III,
(From 10 years) H IV,
(From 12 years) HV.
5. Such of the following as are applicable:
(From 6 years) H VI,
(From 7 years) H XIII,
(From 9 years) H XII.
6. (From 14 years) prose completion, labyrinths, and K adult 7.

B. Non-English speaking subjects:—

1. K, to obtain rating, if possible.

Note, (1) that the repetition of digits is a test of very unequal difficulty in different languages; (2) that the average interpreter, who is not a

psychologist, cannot be relied upon to translate problem questions and their answers without modifying their value for examination purposes (questions like K XII 2, 3 and 4 fall under this suspicion); and (3) that memory tests involving narrative, such as K XI 3, are, in like manner, of doubtful value when given through an interpreter.

2. One of the following tests:

- (4-9 years) H I,
- (From 9 years) H XXIII.

3. One of the following tests:

- (From 8 years) H III,
- (From 10 years) H IV,
- (From 12 years) H V.

4. (From 14 years) labyrinths, and K adult 7.

V. ILLITERATES.

1. K, to obtain rating.
2. Y, omitting No. 18.
3. Such of the following tests as are applicable: B VI 1, VII 1, VIII 4, IX 1, X 1.
4. One of the following tests:
(3-9 years) H I,
(From 9 years) H XXIII.

VI. NON-ENGLISH SPEAKING SUBJECTS.

1. K, to obtain rating, if possible (see above, IV B 1 note).
2. Such of the following tests as are applicable:
Y 1 = B VI 5,
Y 2 = B VII 3,
Y 3 = B IV 4 and V I,
Y 16 = B X 2.
3. (From 9 years) for subjects familiar with our money, B IX 1 and X 1.
4. (From 10 years) B X 4.
5. One of the following tests:
(3-9 years) H I,
(From 9 years) H XXIII.
6. Such of the following tests as are applicable:
(From 7 years) H VIII,
(From 8 years) H III,
(From 10 years) H IV,
(From 12 years) HV and XVI.

REMARKS ON CLASSIFICATION OF CASES.

Most of the cases fall into one of three classes, those that may be described as precautionary, the mental problems, and the social problems.

Under the first head come those subjects who have given no evidence of abnormality. Such individuals are sometimes examined because of abnormality in other members of the family, and sometimes they are referred from some social agency which has recently taken charge of them, the mental examination being utilized as one means to a more certain understanding of their needs and capabilities.

In such cases, a favorable result of the routine examination usually closes the case, at least for the time. That is, it is sufficient if the subject is found to be mentally normal or advanced, or suffering only such slight retardation as may be abundantly accounted for by known conditions.

Sometimes, however, a more searching examination is especially requested, and then the examiner must use his judgment as to the additional tests to be employed. From the "history" of the case, or from conversation with the subject or with the person accompanying him, or from the record made already on the routine examination, it may appear that certain traits deserve special study. In general, it may be said that, with children up to about twelve years of age, learning capacity is of prime importance; while, with older subjects, practical judgment and constructive imagination should be stressed.

Under the second head come those patients who have given definite evidence of mental deficiency, such as children who repeatedly fail of promotion in school. This class, again, may be separated into two groups according as the individuals react normally in some relations or in none.

Occasionally a subject, presented as an all around defective, makes a normal record on the tests, and one is forced to conclude that the defect is in the environment, or possibly in some highly specialized function which the tests fail to reach. In such a case, additional tests may be given in order to strengthen the evidence for a conclusion which will be, at least unexpected, and possibly even unwelcome. Generally, however, such subjects do not react normally to the tests, and the task of the examiner is to determine the amount of deficiency and the sort of care likely to be necessary.

On the other hand, if it is only in certain relations that evidence of defect appears, there is much greater likelihood that the score by the Binet or the Point Scale may be normal. A child, for example, may be quite backward in school, but apparently normal in all other ways, and his backwardness may turn out to be due to general mental defect (an arrest of development which is just beginning to show itself), to a specialized defect, or to unfavorable environment. If the examination indicates normal mentality, that may be sufficient if the environment is known to be doubtful and can be improved. Otherwise, one should look for some specialized defect, such as poor visual memory; and, also, for any specialized ability which might be utilized as compensation for the defect. Thus, if suitable training could be given, good practical judgment might combine with strong kinaesthetic memory to atone for a considerable deficiency in visual verbal memory.

If a subject proves to be seriously defective, the question arises as to the kind and amount of care required. The guardians need data on

which to base decisions as to custodial or institutional care, and as to whether the subject can probably earn his own living, and, if so, by what sort of labor and with how much supervision. The decisive factor in the case is often a matter of social reactions, but the mental examination should contribute its share towards the solution. Important points are motor co-ordination, attention, ability to learn by experience, auditory memory, practical judgment, stock of ordinary information and ability to acquire such, and suggestibility.

The problems classed as social are met at all ages, but more frequently as the age increases, until by sixteen or seventeen nearly all fall into this group. It includes, besides court cases and delinquent girls, many economic cases, individuals from fourteen upwards who either refuse to work or fail to keep any position, and unstable individuals, as, for example, children who are said to be unmanageable, having violent fits of temper and perhaps cruel to younger children.

The origin of the trouble may lie in an unfavorable environment, a general mental defect, some mental peculiarity, or a combination of these.

Here are found a large proportion of sub-normal and borderline cases. An individual may develop fairly well up to twelve or thirteen years, and then suffer an arrest of mental development. If he leaves school early to go to work, the school record may give no evidence of excessive retardation. A mental examination at fifteen may fail to give conclusive evidence; but it may show, for example, high suggestibility, and slow, inaccurate or inappropriate reactions. It is well then to request a second examination after six months or a year.

Sometimes the Point Scale examination shows a distinctly good mentality, and then a few supplementary tests may furnish indications of abilities that would repay training. Occasionally the whole trouble arises from the fact that an able individual lacks suitable outlet for his energies.

Roughly speaking the significant functions are likely to include, for court cases and delinquents, practical judgment, constructive imagination, suggestibility, and reaction-time; and, for economic cases, attention, auditory memory, and ability to learn by experience; while, in all social cases, abnormalities of the affective life are likely to be present.

When a psychosis is present or suspected, the examination should stress motor co-ordination, attention, memory (including "information" tests as well as those ordinarily grouped under memory), suggestibility, and imagination.

For examination purposes, the illiterates and the non-English speaking subjects form groups by themselves, regardless, to a considerable degree, of the problem involved.

The illiterates are generally immigration cases, the practical question being whether they

shall be admitted or deported. Important facts to be determined are the subject's ability to learn by imitation or by experience in concrete situations; to analyze such a situation and to plan on the basis of that analysis; to acquire, retain and use practical information, and, for English speaking subjects especially, to comprehend and to follow verbal instructions.

The non-English speaking subjects include, besides immigrant cases, not a few individuals who have been in this country for a number of years. Typical cases of this sort are the Hebrew women from Russia, who have had no formal education in their old home, and who come to this country after they have been married several years. They usually live in Hebrew communities, and the care of home and children confines them so closely that years may pass without their learning more than an occasional word of English.

ANALYSIS OF TWO ILLUSTRATIVE CASES.

To illustrate the practical working of these programs, two cases, one mental and one social, will now be analyzed.

A MENTAL PROBLEM.

Let us suppose a boy of 13.4 years is brought for examination because he failed of promotion in school last year and bids fair to fail again this year. He is said to appear bright enough out of school, and to be normal in most ways; but he is a state ward, little is known of his people, and an arrest of mental development is feared.

He is prepossessing and responsive, and makes a favorable impression on the examiner.

The result of the Point Scale examination is a score of 82 points. He belongs to the unfavored, English speaking class, and the graph for that class shows 79 to be the norm for his age. It also shows 82 to be the norm for 15 years. Apparently, then, there is no general retardation. It remains to investigate the possibility of a specialized defect, and, if that is found, of special abilities which may tend to compensate for it.

His Point Scale record shows that, in the repetition of sentences, he gave only the first group correctly; in the repetition of digits he gave five correctly, but failed on six; he gave 70 words in 3 minutes; attempting to use three given words in one sentence, he formed a compound sentence, which counts as two; he failed to define justice, knowing only Justice of the Peace; of the analogies, he was able to complete but three; in drawing from memory, he obtained one point credit on each figure; and he failed entirely on the third of the dissected sentences.

The indications, thus far, are of a memory de-

fect, with a development of the reasoning powers which is somewhat in advance of his age.

We next fill out the Binet record sheet (Godard's revision) as far as may be from the Point Scale record. The first failure occurs at V 3. As this is a test of memory span, and there is no other failure until X 2 is reached, we compromise and begin at VIII. He succeeds with these, and we pass on to IX 1, 3 and 4. He gives the change in IX 1 accurately and promptly, returning one of the dimes and picking out a nickel and a copper for the six cents. On IX 3, he fails to give the year, and we find that though he has read it and heard it repeatedly he has rarely had occasion to write it. He gives correctly the day of the week, remarking that "yesterday was Sunday," and, after a slight hesitation, the month and the day of the month, adding "tomorrow will be St. Patrick's Day." He fails in IX 4, making two errors, one omission and one inversion. He passes on X 1 and XII 5, but fails on XI 4. Thus he makes a record of 10.6 years (if we ignore the failure on V 3), and we find here still further evidence of good reasoning power with poor memory.

H XXIII is finished in 6 minutes with no errors.

H IV, first trial, OK in 2 minutes, with 3 errors; second trial, OK in 1 minute, with no errors.

H VIII, no errors, neat work, with no hesitation.

H XII and XIII, 12 out of 20, and 7 out of 12 details, respectively; in both cases in logical order, but with no attempt at verbal accuracy.

We, therefore, conclude that the boy is not mentally retarded; that he has a specialized memory defect, namely, very poor verbal memory whether for visual or auditory presentation; that his memory is apparently of the motor type; and that his logical faculty and practical judgment are somewhat in advance of his age.

It is probable that the methods of the ordinary school are ill adapted to him, inasmuch as they involve a good deal of verbal memory.

There is the possibility that we are dealing here with a peculiarity of development and not with a permanent condition. It would be well, for the present, to give him the help of a special teacher or a special class. If he continues, even then, to lose ground he should be given a chance in a technical or a trade school.

We should like to examine him again in about a year.

A SOCIAL PROBLEM.

A common type of social problem is the adult who fails to earn a living. A woman of twenty-five, for example, is sent in by the Associated Charities, who report that she comes of sturdy, hard-working people, and that her brothers and sisters have done well in their various ways and in proportion to their opportunities; but that he has drifted from one position to another ever

since she left school at fourteen. Her employers say that she is strong and willing, and pleasant to deal with, but that she does not learn to do even the simplest work properly, that she cannot be trusted to do an errand correctly, and that she sometimes leaves a place without notice and without apparent reason.

On the Point Scale she scores 50, the norm for 8.7 years, whereas an adult should make 90 points. She can repeat only three digits, and only the shortest group of sentences. So far her record resembles the preceding, but in her case it is no specialized defect. She scores only two points on the backward counting. She fails to interpret any of the Binet pictures, but gives very passable descriptions. In comparing remembered objects, she succeeds in giving only one point of difference for each pair, and her definitions of concrete terms are all in terms of use. She gives only 50 words in 3 minutes; fails entirely to compose a sentence with the three given words (she makes a separate sentence for each word); and comprehends only the first two of the four questions in No. 15. She fails on both drawings in No. 16, detects only the first two of the absurdities, and fails on all three of the dissected sentences. She is able to define charity, but not obedience or justice, and she solves only the first of the six analogies.

It is a clear case of feeble-mindedness, and the problem now takes the form of a question as to whether she can probably earn her own living under any conditions, and whether she requires custodial or institutional care.

To obtain the Binet rating, we transfer the record as before to the Binet sheet. We then see that, thus far, she has scored no success above nine years, except XII 4, which is not always significant, and that her failures begin with V 3. As this is not a case of specialized defect, we give IV 1 and 2, both of which she passes, thus making a clear score at the four-year level. Working upward, we find that she succeeds with V 4, but fails on V 5 ("patience"). She passes all again at VI and VII. At VIII, she gives the days of the week correctly, but fails on counting the stamps. At IX, she fails on 1, 3 and 4, giving rather complacently thirteen coppers in change, failing to give anything beyond the day of the week in 3, and naming only seven of the twelve months, and those in irregular order. At X, she recognizes the money correctly. At XI, she fails entirely on the rhymes. Her Binet record, therefore, stands as follows: all right at IV, 3 right at V, all right at VI and VII, 2 at VIII, 1 at IX, 1 at X, none at XI, and 1 at XII. Her Binet age will be 7.6 years if we reckon from the four-year level, or 8 years if we take seven years as the starting point. In the latter case, it should be noted that failures occurred at the five-year level.

Even if the Binet rating were not desired, we should probably give the coin and calendar tests to a subject of this type. Her failures in them

show her incapacity for holding her own in business relations. A woman over twenty years old, who has always belonged to the class of unskilled laborers, and who has not acquired this much practical information is clearly incompetent to manage her own affairs.

The next question is whether her failure to master simple tasks is due to herself or to her environment.

H XXIII is incomplete after 10 minutes. She has placed 5 pieces correctly, made 2 logical and 2 illogical errors, and is still experimenting with the tenth square.

At H VIII she works willingly, but with three errors and one omission in the graphic learning, and four errors and an omission in the reproduction.

In H XIII, she is able to reproduce only two of the twelve details.

In H III, she uses the method of trial and error, and succeeds after three minutes with ten extra moves, the same error being repeated in several instances. She is pleased with her success, and we decide to repeat this as a supplementary test in order to observe the effect of practice. The result is a failure after three minutes.

In H IV, she fails after 8 minutes, making 24 moves and placing correctly only 4 pieces.

In H XVI, she makes a good record as regards both speed and accuracy.

As a second supplementary test, H VI is given. She gives a fair description, but no interpretation, and several details of her free recital are imaginary. Under questioning she is very inaccurate, and she accepts nearly every suggestion offered.

Apparently her learning capacity and ability to profit by experience are very slight; she has little or no ability to plan; her auditory memory is very poor and her suggestibility high.

On the other hand, we notice that with all her blunders on the puzzles she handled the pieces with considerable deftness, her square and diamond were well and firmly drawn, she was successful in the discrimination of weights, and did well in the tapping test. Moreover, she is doing rather better towards the close of the examination than in the beginning.

We, therefore, conclude that she is feeble-minded; that she will require custodial, if not institutional, care; but that, with supervision, she should prove a good worker at simple tasks.

As a matter of fact, such an individual must generally be placed in an institution sooner or later on account of the difficulty of providing adequate supervision elsewhere. Her high suggestibility in combination with the lack of reasoning power and of ability to learn by experience would make her a ready tool or victim, as the case might be, of the unscrupulous.

Reports of Societies

CARNEY HOSPITAL CLINICAL MEETING.

CLINICAL MEETING OF THE STAFF OF THE CARNEY HOSPITAL IN THE HOSPITAL BUILDING. THURSDAY, APRIL 22, 1915, AT 8.15 P.M.

DR. LEEN, *Chairman*.

(1) DR. JOHNSON reported two cases:

a. A case of carcinoma of the vaginal vault. Twenty-one years ago the patient had both tubes and ovaries removed for inflammatory disease, by abdominal operation. Two years later the uterus was removed per vaginam, for pelvic pain and discomfort. Neither on curetting nor on hysterectomy was there any trace of cancer. The patient was perfectly well following the second operation, until recently, when a slight bleeding from the vagina was noticed. There was found on examination a small mass in the vaginal vault, which proved, under the microscope, to be carcinoma. Radical operation was out of the question. This seems to be a case of primary carcinoma of the vagina, a comparatively rare condition.

b. A case of normal pregnancy in the third month. One year ago the patient complained of abdominal pain and was operated on; the right ovary, a dermoid, was removed and about four-fifths of the left ovary was resected for cystic disease. A feature of the case was the presence of every presumptive sign of pregnancy.

(2) DR. HEPBURN showed two cases of bone syphilis from the surgical out-patient.

a. A girl of nine fell while roller-skating, injuring her right arm which quickly showed a swelling. After trying home remedies for two or three days, she was brought to the out-patient department. There was found a nodular swelling of the upper half of the ulna, and it seemed probable that a subperiosteal fracture had taken place. The x-ray showed no fracture but the Wassermann was four plus.

b. A man of thirty-eight showed a macular eruption of the left leg with some superficial ulcerations and thickening of the tibia. Treatment for rheumatism had been given at some other hospital, the patient said, but the x-ray showed destruction of bone in addition to the thickening and the Wassermann was four plus.

(3) DR. RUSHMORE showed two cases that had been operated on for prolapse of the uterus.

a. A woman of fifty-four, whose prolapse began over six years ago. Six years ago she had undergone plastic operations, but the prolapse recurred in a few months. Later an abdominal supravaginal hysterectomy was performed, with recurrence of the prolapse in a few weeks. The operation which was performed two weeks ago was to suture the cervical stump into the abdominal wall by non-absorbable sutures, without tension. Hysterectomy makes these cases more difficult to cure as it gives a smaller mass of tissue to incorporate in the abdominal wall. An extensive plastic below also was done. The immediate result is perfectly satisfactory.

b. The second case was one of incomplete prolapse; though the protruding mass was three inches in diameter, the fundus was still in the pelvis. The

patient was seventy-four years of age, with chronic bronchitis, blood pressure of 170 mm., slight swelling of the feet and occasional irregular heart action, with no sign of valvular disease or disturbed renal function on two examinations of the urine. The need of relief was urgent as the patient was helpless with the protruding mass, but an extensive operation under ether seemed ill advised. It was thought best to fix the uterus to the anterior abdominal wall, and thus give at least some relief for the few remaining years of life. Under local anesthesia the abdomen was opened, but the uterus could not be lifted from its position low in the pelvis without causing undue pain. A little ether was given to complete the operation, which consisted in incorporating the uterus with the abdominal wall. Four non-absorbable sutures were used, passing through fascia of recti and deeply into the muscle of the uterus. This gave also a large area in which adhesions may form to assist the sutures. The immediate result is perfectly satisfactory.

(4) DR. LEEN showed three cases.

a. Recurrent gallstones. A man of forty-seven, who had been operated on at the Massachusetts General Hospital seven years ago for gallstones. Stones were found in the gall-bladder and in the hepatic duct. There was also a stone in the common duct, which disappeared after manipulation, but fragments of stone were recovered from the common duct. The convalescence was perfectly satisfactory and the patient was well up to one year ago. Then occurred an attack of abdominal pain with slightly blood-stained vomitus. Five weeks ago a similar attack, followed by loss of seventeen pounds of weight. Four days before admission, another attack, with severe lancinating pain, originating apparently in the right upper quadrant but marked also on the left, and lower down. Greenish vomitus but no blood. On admission there was a suggestion of icterus, temperature 102.5, tenderness over the region of the gall-bladder, leukocytes 20,000. He was seen in consultation with Dr. Bottomley who advised operation which the patient refused. He is improving daily. In the absence of operation the diagnosis must remain in some doubt but recurrent gallstones seems most likely.

b. Hydropneumothorax. A man of twenty-eight years whose family and past history were negative except that he had pneumonia twice in childhood. Two weeks ago, frontal headache and pain in the right side of the chest which gradually became worse, but did not interfere with work until four days before admission. No history of exposure to undue heat or cold. No tonsillitis. There had been a dry cough since the beginning of the present illness, but no shortness of breath and no palpitation of the heart. On the day of admission before he came to the hospital his chest was tapped by his physician. On admission he looked rather sick and was found to have a clearly marked hydro-pneumothorax of the right side, the heart markedly displaced to the left of the median line. Succussion was easily made out. The examination of the sputum so far has shown no sign of tuberculosis.

c. Tetanus. A boy who four weeks ago and two weeks before admission injured his foot on a nail. On admission, temperature 103; typical facies of tetanus with risus sardonius, opisthotonos and general contraction of muscles. He has received in all twenty-one thousand units of antitoxin, intraven-

ously and intraspinously and is now well on the way to recovery.

(5) DR. O'HARE spoke on experimental study of renal function. The object of the study in which he had been particularly interested is to obtain a simple short and efficacious test of renal function. These criteria no test as yet satisfies. The objections to the present methods were discussed. The comparison of the nitrogen and the salt in the blood and in the urine at the same time, offers the most hopeful outlook for a satisfactory method at the present time.

(6) DR. A. R. MACAUSLAND showed two shoulder cases for Dr. W. R. MACAUSLAND.

a. Subglenoid dislocation in a boy of long standing, apparently since infancy, and

b. Ankylosis in a girl. Both cases were under treatment and showed improvement.

He then spoke at some length on separation of the epiphysis of the head of the femur, reporting five cases with x-rays, and showing two cases now under treatment in the hospital. These two cases represented two types, the "fat boy" and the anemic individual; both had been treated for some other condition of the hip which was not present. The history is typical in many of the cases, and the x-ray easily confirmatory, yet the cases are often treated for tuberculosis of the hip.

c. Exhibition of two cases, with x-rays, of fracture of the tarsal scaphoid.

(7) DR. MAHONEY showed a patient who had been operated for a breast tumor which weighed fifteen pounds on removal. Photographs gave an excellent idea of the gross relations. The patient was single, thirty years of age. Five years ago noticed a lump in the right breast which appeared following a trauma, with slight discoloration of the skin. Never sore or painful until of late. Gradual increase in size, giving a dragging pain. In the past year menstruation has been very slight, the tumor has increased more rapidly and the swelling has not decreased following menstruation as the patient says was formerly the case. At operation numerous large glands were removed from the axilla. The microscopical diagnosis was adenofibrosarcoma.

(8) DR. BUTLER showed lantern slides of x-rays of a number of intra-abdominal conditions, as ulcer of the duodenum, cancer of the stomach, gall-stone disease, cancer of the large intestine, hour-glass stomach and adhesions due to tuberculosis of the bowel and peritoneum.

(9) DR. LEEN showed a case of relapsing fever. The patient, an Armenian, showed on admission nothing but a slight cold. He was kept under observation for several days and about to be discharged when he had a sudden elevation of temperature to 103, and the spirochete of relapsing fever was found in his blood that night. Slides were shown with the spirochete easily visible. Dr. Leen then gave a lantern slide demonstration of the spirochete of relapsing fever and of syphilis, the trichina and filaria, and an extended series showing the evolution of the parasite in uncinariasis.

STEPHEN RUSHMORE, *Secretary.*

Book Reviews.

Urinary Analysis and Diagnosis by Microscopic and Chemical Examination. By LEWIS HEITZMANN, M.D., New York. Third revised and enlarged edition. New York: William Wood and Company. 1915.

In this third edition of a well-known text-book on urinalysis, the author has attempted to incorporate the many advances made since the appearance of its immediate predecessor. The work is divided into three parts. In the first, on chemical examination, the aim has been to include all the simpler methods and tests. Many new tests have been added but the more complicated tests are omitted. The second part, on microscopic examination, bears the chief stress of the work, and in it the author emphasizes his belief that correct diagnosis can generally be made by careful high power study of urinary sediment. In the third part, on microscopic diagnosis, a number of full page illustrations have been added and the entire work is now illustrated with 131 figures, mostly original. An appendix contains a standard form for report of urinalysis and a list of apparatus and re-agents required. The illustrations are useful and accurate, though often not artistic, and the book should prove of definite value to students and practitioners, especially in the field of clinical microscopy.

Clinical Diagnosis. A Manual of Laboratory Methods. By JAMES CAMPBELL TODD, Ph.B., M.D. Illustrated. Third edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company.

The first edition of this work, published under the title of "A Manual of Clinical Diagnosis," was reviewed in the issue of the JOURNAL for January 21, 1909 (Vol. clx, p. 81); and the second edition under the present title, in the issue of the JOURNAL for June 20, 1912 (Vol. clxvi, p. 935). In this third edition the general scope of the work is again somewhat enlarged, chiefly by the addition of new material as the outgrowth of questions arising in the class and laboratory. Considerable additions have been made, especially to the chapters on sputum, urine and animal parasites. The chapter on the use of the microscope has been enlarged and the section on cerebro-spinal fluid rewritten in the light of recent advances in knowledge. Numerous new methods of laboratory diagnosis are included and a new chapter has been added on sero-diagnostic methods by Dr. Ross C. Whitman, professor of surgical pathology and serology in the University of Colorado. The number of illustrations has been increased by thirty-five, the new figures being chiefly photomicrographs. The work should continue to be of practical usefulness to students and practitioners.

Practical Tropical Sanitation. By W. ALEX MEYRHEAD. New York: E. P. Dutton and Company. 1915.

This British treatise on tropical sanitation, dedicated to Sir Ronald Ross, represents the experience of a royal army medical officer in West Africa. It is intended as a manual for sanitary inspectors and others interested in the prevention of disease in tropical and subtropical countries. The text is based on the author's lecture notes used at the School of Army Sanitation at Aldershot. The treatment of the subject is wholly practical, theory and experimental research being almost wholly eliminated. The appendix contains a large amount of valuable material chiefly of a technical nature. The work is well illustrated with 114 figures. It should prove of definite practical value for army officers and others engaged in field work in the prevention and control of tropical diseases.

The Origin and Nature of the Emotions. By GEORGE W. CRILE, M.D. Edited by AMY F. ROWLAND, B.S. Philadelphia and London: W. B. Saunders and Company. 1915.

This volume of miscellaneous papers, consisting of a series of eight essays and addresses delivered on various occasions, may be regarded as a supplement to the author's works already published on the subject of surgical shock and the nature of anoci-association. The first of these addresses was the ether day oration at the Massachusetts General Hospital in 1910, published in the issue of the JOURNAL for Dec. 8, 1910 (Vol. clxiii, p. 893). Other addresses present his theory of the relation of phylogenetic association to the emotions, and the relation between brain functions and the physical state of brain cells. Dr. Crile takes a mechanistic view of psychology and undertakes to establish a mechanistic theory of disease. The tendency of both these concepts bears a striking parallelism to Loeb's mechanistic conception of life. However one may agree or disagree with Dr. Crile's deductions, which, like most conclusions from postulated theory are, perhaps, carried unwarrantably far, his work remains a valuable and suggestive contribution, both to surgical research and to biologic philosophy.

The Sun Cure. By DR. A. ROLLIER. Paris: Baillière and Son. 1914.

This French monograph presents the results of ten years' work by the author in the development of the method of sunlight cure in the treatment of surgical tuberculosis. However radical his methods may appear, his results have, within recent years, become known and seem, in considerable measure, to justify the procedures. The

book is abundantly illustrated with many colored plates, radiographs and figures in the text.

Legal Principles of Public Health Administration. By HENRY BIXBY HELMSWAY, A.M., M.D. Chicago: T. H. Flood and Company. 1914.

This text-book of legal appearance aims to present for the benefit both of lawyers and of physicians the legislative and judicial principles upon which public health administration is based. Compilations and analyses of public health laws have previously been published, but this is the first modern treatise to attempt the scientific legal exposition of the principles of public health and preventive medicine. The introduction by Professor John Henry Wigmore of Northwestern University emphasizes the importance of such a work as a basis of precedent and authority in legal decisions. The author's foreword calls attention also to the necessity of a recognized legal code underlying all attempts at public health improvement and regulation. The text is divided into two parts, the first dealing with general principles, the second with special topics such as quarantine, licenses, water supplies, drainage, garbage disposal, pure food, drug and industrial regulation, school inspection and engineries. This last chapter is one of especial interest. On account of the still rudimentary character of this science, so far as it is positively developed, the chapter is necessarily brief, but so far as it goes, may be regarded as sound and conservative. The volume closes with an extensive index of cases cited and a general index to the text. It should be a work of value to physicians purposing to engage in public health studies or work, as well as to lawyers and legislators who may be concerned in similar matters.

State Registration for Nurses. By LOUIE CROFT BOYD, R.N. Second edition. Philadelphia and London: W. B. Saunders Company. 1915.

The first edition of this monograph was reviewed in the issue of the JOURNAL for June 22, 1911 (Vol. clxiv, p. 896). This second enlarged edition represents the growth of the corresponding material during the past four years. It contains the same headings as the previous edition with the exception that the excellent bibliography of the first edition has been replaced by the full text of the laws prevailing in the various states of the union, relative to the registration of nurses. This text constitutes the bulk of the increase in the size of the book, but it seems a pity that its inclusion should have been felt to necessitate the elimination of the bibliography. Like its predecessor, this publication should be of value to all interested in the profession of nursing and its legal status.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JUNE 17, 1915.

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*
WALTER L. BURRAGE, M.D. } *For the Massachusetts Medical Society.*
FREDERICK T. LORD, M.D. }

COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D. ALLAN J. McLAUGHLIN, M.D.
HARVEY CUSHING, M.D. ROBERT B. OSGOOD, M.D.
DAVID L. EDSELL, M.D. MILTON J. ROSENAU, M.D.
REID HUNT, M.D. EDWARD C. STREETER, M.D.
ROGER I. LEE, M.D. E. W. TAYLOR, M.D.

ADVISORY COMMITTEE.

EDWARD C. STREET, M.D., *Boston, Chairman.*
WALTER P. BOWERS, M.D., *Clinton.*
HOMER GAGE, M.D., *Worcester.*
JOEL E. GOLDTHWAIT, M.D., *Boston.*
LYMAN A. JONES, M.D., *North Adams.*
HUGH WILLIAMS, M.D., *Boston.*
ALFRED WORCESTER, M.D., *Waltham.*
ROBERT B. OSGOOD, M.D., *Boston, Secretary.*

ERNEST GREGORY, *Manager.* W. M. LEONARD, *Consulting Manager.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

PHYSICAL TYPES IN THE HUMAN BEING.

There is abundant evidence that the past ages produced their observers no less keen than we can boast: it is even to be questioned if the increasing cloud of specialties has not tended to make for short-range vision. Certain it is that no modern has improved much upon the description given some 2400 years ago by Hippocrates or 2000 years ago by Lucretius of a disease so characteristic and unchanging in its manifestations as epilepsy.¹

It is equally certain that for at least 2000 years there has been a consciousness of the division of the human race into opposing types. Thus Plutarch² makes Caesar say in substance, "As for those fat men and smooth combed heads, I never reckon of them; but these pale-visaged and carrion lean people, I fear them most." These words as later paraphrased by Shakespeare³ are worth reading as a graphic descrip-

tion of the mentality of the carnivore. Nursery rhymes such as "Jack Spratt," attest the same appreciation of type by the so-called common people. More recently, in the scientific world, Hall⁴ has stated that infant nature divides sharply into two types, the passive and the active—precursors of those recognized in the adult by Caesar.

Since 1890 or so, interest in general fundamentals seemed to have yielded to detail work; but lately a healthy interest in these broader aspects of medicine is again apparent. Thus the question of type and development has been approached on biologic grounds as evidenced by the papers of Bean⁵ and others. Recently we had occasion to refer to the first of a series of papers by Bryant⁶ on this subject of type, the second of which is about to appear. In this issue we present as the current Shattuck lecture, a review of our existing knowledge of type and its potential usefulness to medicine of the future. Dr. Goldthwait under the title of "An Anatomic and Mechanistic Conception of Disease," has based his argument upon his own observations and those of others, and has thrown the burden of proof that type does not exist, or existing is unimportant, upon those who, like the anti-vaccinationists, refuse to be convinced by well supported facts. The case for the existence of type may be considered closed and proved.

The study of type has come to stay, to be a powerful factor in constructive work of the future. Many basic problems present themselves, as the effect of diet and climate upon type, and the relation of both these factors to the evolution of type in a given locality. Thus Cattell⁷ has recently argued that climate has a striking influence upon mentality, and Ellsworth Huntington⁸ believes that climate may be a determinator of civilization.

Education is, however, the real question at issue. All the facts may be correct, but if they remain unknown for years they must needs be discovered anew as were Mendel's laws, before they become useful. Dr. Goldthwait in his deductions has covered the field of possibilities, indications and necessities so thoroughly that little can be said except in reinforcement of his remarks. He has shown at least some of the definite meanings of type for the physician alert to new paths to efficiency. He has considered the present tendency, due in part to the increasing prevention of natural elimination of the unfit, toward the carnivorous type with both its

good and bad qualities, and suggested methods by which the tendency of the race in this part of the world may be turned to positive good account for the future. But of greatest moment is his statement that the coming importance of the understanding of type will necessitate a new method of teaching anatomy, physiology and the allied sciences.

The time is in all certainty soon coming when it will no longer be taught as at present in the best schools that, for example, the human intestine is so many feet long, and that measurements obtained above and below this figure are variations from the normal. It will, on the contrary, be recognized that there are two structurally, functionally, absolutely different types, both normal of their kind. One type will have perhaps double the length of intestine to be found in the other; the text book's normal of old will lie somewhere between these extremes, and will be of less consequence than either, for the ailing patient will probably fall either one side of the normal or the other, according to his type. But after all, the time will come when the student will acquire this newer knowledge in his routine instruction.

The vital issue is the instructing of present medical graduates upon whom devolve the care of patients now, before the arrival of the next generation of doctors and educators. The opinion is ventured that not one in a hundred of the intelligent medical men now in practise have ever heard of type, or having heard, realize what it may mean to them or to their patients. How many men are there who, looking at a man in the street, can give an approximately correct outline of the anatomy and internal physiology of the stranger? Yet for the medical man this or something like it should be common knowledge.

If repetition, reiteration without irritation, be the key to education in a new subject, then it behooves us to reiterate that the essayist has in his discussion of type projected a ray of light into the medical teaching of the future. Having said it, we repeat it in the faith that truth repeated brings conviction save where densest

ignorance prevails. Some medical school will be the first to incorporate lectures on type in its curriculum. The others will follow where they can no longer lead, giving to student and patient alike the benefit of this newer knowledge of type, this newest aid to the science and art of medicine.

INJECTION OF THE SPHENO-PALATINE GANGLION.

In recent years there is a noticeable tendency to reach parts of the nervous system which are not easy of approach, in our therapeutic endeavors to relieve the pains which could not very well be alleviated satisfactorily in other ways. In this connection we may mention injections into the peripheral nerves, particularly the trifacial, epidural injections and perineural infiltrations for the relief of the pains of sub-acute and chronic sciatica, injection into the sphenopalatine ganglia, and, very recently, injection into the Gasserian ganglion.

The use of injection into the sphenopalatine ganglion is not as widely known as it should be, and it is for this purpose that the reader's attention is here called to it. In a paper read before the American Academy of Ophthalmology and Oto-laryngology in 1907, Stein, of Chicago, suggested the injection of alcohol into the nasal nerve and into the region of the sphenopalatine foramen. So far as known, however, Greenfield Sluder, of St. Louis, first made mention of alcoholic injection directly into the sphenopalatine ganglion in the *New York Medical Journal*, August, 1909.

This method of treatment may be employed in four general conditions, as follows: hay fever, the syndrome of true sphenopalatine neuralgia, hyperesthetic rhinitis, and post-operative neuralgia. In true sphenopalatine neuralgia there is pain in the region supplied by the branches of the ganglion, the typical location being over the root of the nose, in and about the eye, over the frontal region, and even radiating into the pharynx and tonsil, the ear, the mastoid and occipital region, and not rarely into the neck, shoulder, arm and even fingers. This condition is usually associated with suppuration in the sphenoid sinus and ethmoid cells, the pain persisting after proper surgical treatment of the sinuses and cells has been instituted. In a small number of these cases it is found that the pain

first makes its appearance after thorough opening and draining of the accessory sinuses has been carried out for the relief of the chronic suppurative sphenoiditis and ethmoiditis. It is these cases which are properly referred to as post-operative neuralgia of the spheno-palatine ganglion. Hyperesthetic rhinitis differs from hay fever in that it makes its appearance at any time of the year, the paroxysms being irregular in their time of appearance, their duration and severity.

The technic of this useful operation as described by Pollock (*Illinois Medical Journal*, May, 1915) is not difficult, there is comparatively no danger associated with the procedure when performed under the usual aseptic conditions, and the results seem to be well worth while. It is, at any rate, a method of treatment which has received but little attention and merits more extensive trial than it has yet had.

DOES INSANITY EVER FOLLOW OPERATION?

The term "post-operative insanity" has become somewhat too prevalent and convenient. There are several objections to it aside from the obvious one, that is, that its existence as a clinical entity may be seriously doubted. In the first place, the term "insanity," expressing as it does a legal rather than a medical concept, should have an extremely limited use, being applied only to cases where a designation of an individual's mental status is required by a legal body to determine his responsibility or his social possibility.

Then, too, by including the term "post-operative" in this designation, we say that the mental disorder followed the operation and imply that it was a sequela of it. There are terms already in use covering practically all psychoses which will be found in such circumstances. For instance, if the trouble was the result of fatigue of the system as a whole, assisted by the condition which led to the operation and aggravated by the extra drain of the operation on the system we may describe it as an "infection exhaustion psychosis." If the psychosis was actually due to the trauma of the operation itself, as in a head operation, we may call it a "traumatic psychosis." If to drugs given before or after

the operation plus the narcosis at the time of operation, it would come under the head of "intoxication psychosis." If the mental disorder is found to be of neurotic origin, as will often prove to be the case, it is a psychoneurosis.

Dr. J. M. Aiken has made an investigation into cases of so-called "post-operative insanity" and reports his results in the *American Journal of the Medical Sciences* for May. He does not believe they occur as the result of the operation itself. He says:—

"Either sepsis, the administration of some drug, or poor judgment by the surgeon who operated on a patient ripe for mental or nervous collapse caused them. Of these three possible factors the latter is probably the most frequent ultimate cause for post-operative psychoses or neuroses."

Dr. Aiken thinks that these conditions were coincidental merely with the operation and would have occurred even in the absence of the latter. Even supposing them to have been the result of the operation, he finds in a majority of cases that they do not outweigh the benefits of the operation.

Let us then dispense with the term "post-operative insanity," if for no other reason than because it may come under the eyes of laymen and add one more prejudice against the surgeon's knife to the possible detriment of a patient who urgently requires operation. But to avoid the appearance of psychoses and neuroses after operation it would be well for surgeons to consult with alienists before operating on patients of manifestly neuropathic tendencies.

MASSACHUSETTS MEDICAL SOCIETY.

THE one hundred and thirty-fourth anniversary of the Massachusetts Medical Society was successfully observed at its annual meeting in Boston last week, of which the complete program was published in the issue of the *JOURNAL* for June 3. Between 600 and 700 Fellows were in attendance. The morning of Tuesday, June 8, was devoted to clinics and demonstrations at the several hospitals. On the afternoon of that day were held the meetings of the sections on medicine, surgery and on tuberculosis. The session of the section on medicine was devoted to a symposium on heart disease. On Tuesday even

ing at the Copley-Plaza Hotel, Dr. Joel E. Goldthwait delivered the Shattuck Lecture on "An Anatomic and Mechanistic Conception of Disease," the full text of which is published in this issue of the JOURNAL with editorial comment in another column. Following the lecture there was an informal reception to the president with music and refreshments.

The annual meeting of the society was held on the morning of Wednesday, June 9, and the papers constituted a symposium on preventable diseases from the standpoint of public health and preventive medicine. Following this program, Dr. Everett A. Bates of Springfield delivered the annual discourse at noon on "Some Perplexities in Modern Medicine," the complete text of which was published in last week's issue of the JOURNAL. The combined meeting of the sections of medicine and surgery, held on Wednesday afternoon at the Boston City Hospital, was devoted to a symposium on empyema. The complete text of all these papers, with full report of the discussion and other proceedings, will appear in subsequent issues of the JOURNAL.

The annual dinner was held at the Copley-Plaza Hotel on the evening of Wednesday, June 9, and was a thoroughly entertaining and successful occasion, attended by over 800 Fellows and guests.

The principal addresses were delivered by Lieutenant-Governor Grafton D. Cushing, Dean Edmund S. Rousmanière, Professor Charles H. Grandgent, and the Honorable William H. Taft. The following officers of the Society were re-elected for the ensuing year: President, Dr. Charles F. Withington; treasurer, Dr. Edward M. Buckingham; and secretary, Dr. Walter L. Burrage.

AN OPERATING ROOM ON WHEELS.

BEARING in mind the ancient adage concerning the parentage of invention, it is not surprising that the exigencies of the present war have called forth many examples of the ingenuity of the medical man. Several models of motor cars containing miniature operating rooms for use at the front have been devised. Their uses are chiefly to serve casualty clearing stations and to take care of cases of grave abdominal injury, head cases and severe wounds necessitating immediate operation. They are not to be used for

removable cases, and it is required of them primarily that they shall be capable of taking the surgeon and anesthetist to the place where they are wanted and provide them with all they require.

One of these cars, designed by Dr. G. H. Colt, of the Aberdeen Royal Infirmary, and now on exhibition in London, seems to be the latest word in ingenuity, convenience and compactness. It consists of two parts, a body and a cab, the former being roughly three times the size of the latter. The car as a whole is six feet, six inches wide, seven feet high, and the wheel base is eleven feet, six inches. The weight of the whole is $2\frac{1}{2}$ tons. The dimensions of the body which contains the operating room are 9 feet 6 inches, by 6 feet 6 inches. Besides the chauffeur, the car carries a surgeon, an assistant, an anesthetist and a nurse. It is capable of making a speed of about 20 miles an hour. The cost of the car itself is \$4350 and the surgical equipment costs about \$1000.

There are so many features worthy of comment about this car that space will not permit mention of half of them. Examples are a tail-board which is so devised that when it is closed the upper surface, over which the patient has been carried, is on the outside. All the boiling and sterilizing is done in the cab, so that some of the most bulky features of the usual operating room are eliminated. The dust is swabbed off the inner walls of the car with a dilute, antiseptic solution of glycerine.

CONSTRUCTION OF LOCAL TUBERCULOSIS HOSPITALS.

In the issue of the JOURNAL for May 13, we commented editorially on the Worrall tuberculosis hospital bill (House 2088), and pointed out the great undesirability of its passage. This bill was referred to the committee on public health, and, at a hearing before this committee, was opposed by Dr. Allan J. McLaughlin, state commissioner of health, on the ground that it was permissive rather than mandatory legislation and did not state specifically when the proposed hospitals should be built by the county commissioners. At the same time he declared himself in favor of a larger hospital unit for the care of tuberculous patients and apparently on the basis of his recommendation the public health

committee filed in the senate on May 25, a substitute measure providing for an investigation by the Massachusetts State Department of Health as to the advisability of establishing county or district hospitals for the care of tuberculosis patients exclusive of cities having 50,000 or more inhabitants. The bill provides that the health department shall report its findings to the next session of the general court.

It may probably be assumed that this substitute measure will effectually shelve the Worrall bill for the present session and by leaving in force the tuberculosis hospital law of 1911, requiring the establishment of local tuberculosis hospitals during the present year, will avoid the retrograde step whose undesirability and dangers we have previously indicated.

MEDICAL NOTES.

NEW YORK DEATH RATE.—The noteworthy feature in the weekly mortality report issued by Commissioner of Health Goldwater for the week ending June 5, 1915, is the saving of 88 lives that would have been lost had the death rate for the corresponding week of last year prevailed during the past week.

The rate for the first twenty-three weeks of 1915 is 14.44, as compared with 15.15 for the corresponding period of 1914.

Several of the infectious diseases show a slight increase, which, however, is offset by reductions in the death toll of other diseases of this group.

The greatest increase is seen under the heading of broncho-pneumonia.

THE ARMY MEDICAL SCHOOL GRADUATION.—The graduating exercises of the Army Medical School, Washington, D.C., were held on June 1. Diplomas were awarded to thirteen graduates. First Lieutenant Harry D. Offutt of Maryland was awarded the Hoff Memorial medal and First Lieutenant Raymond E. Scott, of Missouri, the Sternberg medal.

GIFT TO THE UNIVERSITY OF CALIFORNIA.—It is announced that an annual gift of \$1200 has been offered by a friend of the University of California in memory of Dr. Edith J. Claypole, research associate in the department of pathology, who died on March 26, 1915. This sum will be used to maintain the position which she held and to enable the continuance of the investigation which she had been making in regard to improved methods for immunization against and treatment of typhoid fever.

ASSOCIATION OF AMERICAN PHYSICIANS.—At the recent annual meeting of the Association of American Physicians, held in Washington, D. C., Dr. Henry Sewall of Denver, Colo., was elected president and Dr. George Dock of St. Louis, vice-president for the ensuing year.

AMERICAN NEUROLOGICAL ASSOCIATION.—At the recent annual meeting of the American Neurological Association, held in New York City, Dr. Llewellys F. Barker was elected president for the ensuing year.

GIFT TO INDIANA UNIVERSITY.—It is announced that the University of Indiana has received from Dr. Luther Dana Waterman of Indianapolis, emeritus professor in the Indiana University School of Medicine, a gift of \$100,000, subject to an annuity during his lifetime and on condition that the University shall appropriate an amount equal to the income from the fund. The entire proceeds are to be devoted to scientific research.

EUROPEAN WAR NOTES.—The recent entrance of several more European cities into the zone of warfare gives additional interest to the following table of comparative death rates from diphtheria in times of peace before and after the introduction of antitoxin in its treatment:—

Place.	BEFORE ANTITOXIN. Death Rate Per 10,000 Pop. 1881 to 1890.	SINCE ANTITOXIN. Death Rate Per 10,000 Pop. 1896 to 1910.
Boston	13.7	4.7
New York	16.6	5.27
Philadelphia	11.2	6.7
Chicago	15.4	3.76
Berlin	14.3	2.6
Vienna	6.1	2.4
London	4.1	2.7
Paris	8.1	1.2
Edinburgh	4.2	1.9
Montreal	14.5	4.2
Toronto	9.8	6.3
Rio de Janeiro	2.3	0.5
Brussels	1.1	1.0
Amsterdam	9.5	1.26
Copenhagen	8.4	1.5
Moscow	7.1	5.3
Petrograd	8.3	7.5
Budapest	10.4	2.5
Trieste	12.9	3.2
Milan	9.5	2.7
Turin	5.8	1.2

This table was recently contributed by Dr. Edwin H. Place of Boston in a letter to the daily press on the importance of antitoxin treatment of the disease.

Considerable professional interest attaches to the apparently serious illness of King Constantine of Greece. It is reported that following an attack of influenza, the king recently developed an empyema. On June 5 Dr. von Eiselsberg of Vienna, who had been summoned in consultation, resected a portion of the king's tenth left rib. It is said that pus had been found in the left pleural cavity by aspiration as long ago as May 15. On the day following the operation the

bulletin stated that the king's temperature was 104.8, his pulse 140 and respiration 39. It is believed, however, that these represent the normal septic reaction after operation, and the king's condition is not as yet critical. On June 13, it was reported that the king's temperature was normal and his condition definitely improving.

Report from Nish, Serbia, by way of London, on May 28, states that the Serbian government has issued a call for forty additional American physicians to assist in the suppression of typhus fever and the medical care of the population. There are at present sixteen American physicians in Serbia with Dr. Richard P. Strong and twenty-five with the American Red Cross.

On June 12 the totals of the principal American relief funds for the European war reached the following amounts:—

	N. Y.	N. E.
Belgian Fund		\$262,433.90
Polish Fund	\$63,513.00	46,843.59
Secours National	79,249.44	
Jewish Fund		62,909.52

On June 13 a unit of 32 surgeons and 75 nurses left Chicago, and on June 15 sailed from New York for England to serve with the British Royal Army Medical Corps.

PREVALENCE OF MENINGITIS, POLIOMYELITIS AND SPOTTED FEVER.—In the weekly report of the United States Public Health Service for May 28, it is noted that during the month of April, 38 new cases of cerebrospinal meningitis were reported in Virginia and 18 in Ohio. During the same month there were 23 cases of poliomyelitis in Virginia and 6 in Ohio. Fourteen human cases of Rocky Mountain spotted fever were reported during April in Montana.

TYPHUS FEVER IN MEXICO.—Report from Washington, D.C., on June 8, states that typhus fever is prevalent in Monterey, Mexico, where there is extensive distress among the population. The number of cases is not stated.

"The Red Cross is despatching shortly two additional cars of corn to Monterey. On the *Moro Castle* the Red Cross shipped on June 10 twenty-five cases of drugs and hospital supplies to Consul Canada at Vera Cruz, to be forwarded to Spanish, American and French hospitals in Mexico City. These hospitals are crowded and in great need."

LONDON DEATH RATES IN APRIL.—Statistics recently published show that the total death rate of London in April, 1915, was 19.6 per thousand inhabitants living. Among the several districts and boroughs the highest rate was 27.7 in the precincts of the old city, and the lowest was 12.8 in Lewisham, an open residential region on the south.

SHIPMENT OF RED CROSS SUPPLIES TO SERBIA.—Report from New York on June 8 states that on that day the American Red Cross shipped aboard the steamship *Joannina* to the American consul at the Piræus, Greece, ten automobile trucks for the use of the American Red Cross Sanitary Commission in Serbia.

The shipment also includes eighty-nine tents and forty-two cases of hospital garments, hospital supplies and miscellaneous clothing for the Serbian Red Cross and the American Red Cross hospital units in Belgrade.

TYPHOID FEVER IN ASIA MINOR.—Report from Constantinople by way of Athens states that typhoid fever is now extensively prevalent among the troops and the civilian population in Asia Minor. It is reported that seventy-five physicians have already died there of this disease.

THE SECOND HARVARD SURGICAL UNIT.—It is announced that the second Harvard surgical unit, whose organization we have noted in previous issues of the *JOURNAL*, will sail from New York on June 22, aboard the steamer *Noordam* for Falmouth, Eng., for six months' service in British or French hospitals. The expedition consists of 32 surgeons and 75 nurses, the majority of whom have volunteered for the entire period of service. The personnel of the physicians and surgeons composing this unit is as follows:—

Dr. Edward H. Nichols, surgeon to Boston City Hospital, surgeon in charge of the unit.

Dr. Charles Allen Porter, visiting surgeon to Massachusetts General Hospital.

Dr. Franklin Greene Balch, visiting surgeon to Massachusetts General Hospital.

Dr. Alexander Quaekenboss, visiting ophthalmologist to Massachusetts Charitable Eye and Ear Infirmary.

Dr. Harris Peyton Mosher, visiting surgeon to Throat Department, Massachusetts General Hospital.

Dr. Roger Irving Lee, professor of hygiene, Harvard University and visiting physician to Massachusetts General Hospital.

Dr. William E. Faulkner, assistant visiting surgeon to Boston City Hospital.

Dr. Robert H. Vose, surgeon to Boston Dispensary.

Dr. Allen Greenwood, ophthalmic surgeon to Boston City Hospital.

Dr. Daniel B. Reardon, Quincy, visiting physician to Quincy City Hospital.

Dr. Nathaniel S. Hunting, Quincy, visiting surgeon to Quincy City Hospital.

Dr. Walter M. Lacey, Chyenne, Wyoming, Harvard Medical School, class of 1912.

Dr. Pierce P. McGinn, Somerville, Tufts Medical School, class of 1912.

Dr. John Jenks Thomas, professor of Neurology at Tufts Medical School and visiting neurologist to Boston City Hospital.

Dr. Harry Fairbanks Hartwell, visiting surgeon to out-patient department, Massachusetts General Hospital.

Dr. Pierce Henry Leavitt, Boston City Hospital, Harvard Medical School, class of 1914.

Dr. Charles Wesley Bressler, Harvard Medical School.

Dr. William E. Hunter, Harvard Medical School.

Dr. Philip Duncan Wilson, Harvard Medical School, class of 1914, house surgeon, Massachusetts General Hospital.

Dr. George Warren Bachman, Boston City Hospital.

Dr. Walter J. Dodd, instructor in Roentgenology at Harvard Medical School, x-ray department, Massachusetts General Hospital.

Dr. George Loring Tobey, Jr., assistant visiting surgeon to Massachusetts Charitable Eye and Ear Infirmary.

Dr. Frank Whipple Snow, Newburyport, Harvard Medical School, class of 1902.

Dr. Varazstad H. Kazanjian, demonstrator of prosthetic dentistry, Harvard Dental School.

Dr. Byron B. Stookey, Marine Hospital, Chelsea.

Dr. Harold M. Frost, Boston City Hospital.

Dr. Russell P. Borden, Boston City Hospital.

Dr. Harold M. Goodwin, Boston City Hospital.

Dr. Joseph C. Horan, Harvard Medical School, class of 1915.

Dr. Frederick A. Coller, Ambulance Hospital, Paris.

Dr. Robert R. Sattler, Harvard Medical School, class of 1918.

Dr. E. B. Allen, Harvard Medical School.

Dr. Albert A. Barrows, Providence.

Dr. E. P. Laskey, Haverhill, Mass.

BOSTON AND NEW ENGLAND.

THE CAMPAIGN AGAINST CANCER IN NEW ENGLAND.—The following statement is issued by the press service of the American Society for the Control of Cancer:—

"The New England states generally show a higher death rate from cancer than any other group of states. This does not mean that New England people are more susceptible to this disease. Cancer is a disease of later adult life and it is well known that in parts of New England there are more old people proportionately to the population than in many other regions. Nevertheless, the death rates recently published by the United States Census Bureau have stimulated much activity in these states in the educational campaign for the control of malignant disease.

What are the facts upon which this movement is based? According to the report of the Census Bureau, in 1913 there were 49,928 deaths from cancer in the registration area of the United States, corresponding to a death rate of 78.9 per 100,000 of the population. All the New England states have individual cancer death

rates much higher than this. Connecticut's rate, which is the lowest of any of the New England states, was 85.1. Vermont's rate was the highest with 111.7, while the rates of the other states were correspondingly high, Maine having a rate of 107.5, New Hampshire, 104.4, Massachusetts, 101.4 and Rhode Island, 93.3. When these figures are compared with those of Kentucky, with a rate of 48, they seem indeed very high. They mean that 6,817 people died in 1913 in New England from cancer. But it does not necessarily follow that cancer is more common in New England than elsewhere. The Census Bureau attributes the high cancer death rates in certain districts to the relatively high age distribution of the population and the negligible amount of immigration. Translated into everyday terms this means that in New England the proportion of people over 40 years of age, or at the cancer age, to those under 40, and so less liable to cancer, is greater than in other places. Yet there is no doubt that the cancer death rate in New England as well as in other parts of the country is much higher than it ought to be. Without question a large percentage of cancer deaths can be prevented by early recognition of the symptoms and prompt recourse to competent surgical advice and treatment. Cancer is not a hopeless, incurable affection, as so many people wrongly believe. Those who know the facts believe that if the public can be properly educated in regard to the early signs of the disease and will act on this knowledge, the present mortality should be reduced at least one-half, and perhaps two-thirds.

That New England is awake to this opportunity of saving lives is evident from the activity in several states. Vermont medical men have become so concerned over the high cancer death rate of their state that they recently held a series of meetings on the subject. The New Hampshire State Board of Health has recently published sound advice in its *Bulletin*. In Maine an active committee of the State Medical Society is arranging public lectures and causing the publication of instructive articles in the newspapers. Massachusetts has a well organized branch of the American Society for the Control of Cancer, with headquarters in Boston. The Vermont State Medical Society arranged a series of public meetings to spread the bad news of the high cancer death rate and the good news of the hope of controlling the disease by earlier recognition and prompt surgical treatment. Morning, afternoon and evening meetings were held on Tuesday, Wednesday, Thursday and Friday, June 8th to 11th, at Rutland, Burlington, Montpelier and St. Johnsbury. The Vermont State Board of Health sent its Secretary, Dr. Charles F. Dalton, to address each of these meetings and the American Society for the Control of Cancer was represented by Dr. Francis Carter Wood, Director of Cancer Research at Columbia University, New York City.

and by Dr. J. M. Wainwright, Chairman of the Cancer Committee of the Pennsylvania State Medical Society.

SCARLET FEVER EPIDEMIC IN NEEDHAM.—An outbreak of scarlet fever has been reported in Needham Heights and North Needham. The public schools and churches have been closed and residents have been requested to refrain from attending moving picture theatres and other gatherings. A total of 17 cases has occurred. The source of the infection is not known.

CONCORD DEACONESS HOSPITAL.—It is announced that the Deaconess Hospital at Concord, Mass., has received from an anonymous donor a gift of a private ward building and nurses' home to be built in the rear of the present hospital and completed in the coming fall. The building will be 70 by 30 feet in ground area and will contain eight private rooms on the first floor.

HOSPITAL BEQUESTS.—The will of the late John E. Martin, of Portland, Me., which was filed for probate in that city on June 7, contains bequests of \$50,000 each to the Maine General Hospital and the Maine Eye and Ear Infirmary.

The will of the late Abby Wales Turner, who died in Randolph, Mass., on May 13, was filed on June 8 for probate at Dedham, Mass. Among many public charitable bequests it contains legacies of \$1,000 each to the Sarah Fuller Home for Deaf Children, the New England Hospital for Women and Children and the Brookline Free Hospital for Women.

QUARANTINE FOR FOOT AND MOUTH DISEASE.—Report from Brighton, Mass., on June 8 states that the federal quarantine is still in force over the local stockyards. This quarantine was established in November, 1914, and is not likely to be lifted for several months, although no new cases of the disease have been reported in Massachusetts since May, 1915. Cattle are now being brought, however, to the Brighton stockyards from Maine, New Hampshire and Vermont for immediate slaughter.

EXHIBIT BY STATE BOARD OF INSANITY.—During the past week there was held at the Massachusetts State House by the State Board of Insanity an exhibit of brushes, brooms, boots, hats, rugs and clothing made by inmates of the 13 institutions under the control of the Board. This exhibit which has been announced in previous issues of the JOURNAL, represents not only a therapeutic, but an economic value.

"In several of the hospitals the patients make all of the furniture; in one, all of the straw hats used; in most, the patients are making all the rugs, brooms, brushes and mattresses, and in one they knit by machinery all of the stockings

and sweaters and make all of the clothing of the patients. This is not uniform, but of great variety.

"Today a majority of the patients are employed in useful work—a contrast from former years when they were sitting on benches in the wards with absolutely no occupations. In cases of idiocy and dementia the patients unraveled stockings and pick over mattresses. They work from one to eight hours per day."

SEIZURE OF MILK BOTTLES. Report from Worcester, Mass., states that on June 7 the local commissioner of weights and measures made a seizure of 50,000 paraffined paper milk bottles consigned to a local creamery by a Wisconsin manufacturer. The grounds for the seizure are technical, since the bottles, though properly stamped for use in Wisconsin, were not stamped in accordance with the requirements of the Massachusetts statute.

DEPORTATION OF UNDESIRABLE ALIENS.—The monthly bulletin of the Massachusetts State Department of Health for March, 1915, contains the following important statement relative to the possibility of deportation of certain undesirable aliens within three years of their arrival in this country:—

"It is not generally known that aliens who are suffering from a dangerous contagious disease, insane persons and others who have become a public charge may be deported to Europe at any time within three years after landing, provided their condition is due to causes prior to landing. Lack of knowledge of this fact results in some communities assuming financial burdens which are entirely needless.

"Dr. Allan J. McLaughlin, the Commissioner of Health, has issued a circular letter to district health officers calling their attention to the immigration law and directing them to advise local officials in their districts to avail themselves thereof.

"Aliens suffering from tuberculosis are not admitted to the United States, but many aliens certified as having poor physique, flat chest, underweight for age, anemia and other rather indefinite defects, are admitted. These aliens are excellent material for tuberculosis if they are exposed to slum conditions.

"Some time ago Dr. McLaughlin requested the Commissioner General of Immigration to furnish lists of aliens, destined for Massachusetts cities and towns, having the defects mentioned above. On April 8, Mr. J. B. Densmore, Acting Secretary of the Department of Labor, came from Washington and conferred with Dr. McLaughlin relative to this matter. He agreed to cooperate with the State Department of Health in so far as his appropriation will permit. When these lists are received the Commissioner of Health will then notify the local boards of health, and the tuberculosis dispensary will be able either to prevent the develop-

ment of tuberculosis or to arrange for deportation of the alien at the earliest possible moment if the disease should develop."

NEWTON HOSPITAL TRAINING SCHOOL.—The annual graduation exercises of the Newton (Mass.) Hospital Training School were held in that city on June 2. Diplomas were awarded to a class of 19 pupil candidates.

LONG ISLAND HOSPITAL TRAINING SCHOOL.—The annual graduation exercises of the Long Island Hospital Training School for Nurses were held at that institution on June 3. The principal addresses were made by Dr. Allan J. McLaughlin and Dr. Malcolm Seymour. Diplomas were presented to a class of 17 pupil candidates.

MASSACHUSETTS STATE NURSES' ASSOCIATION.—The twelfth annual meeting of the Massachusetts State Nurses' Association was held in Boston on Saturday, June 5. At the morning session the principal subject of discussion was that of the registration of nurses, and the Massachusetts State League of Nursing Education held a joint session on this subject with the Nurses' Association. At the afternoon session a number of short papers were presented and the following officers were elected for the ensuing year:—

President, Miss Sara E. Parsons of the Massachusetts General Hospital; vice presidents, Miss Mary M. Riddle of the Newton Hospital and Miss Lucia Jacquith of the Worcester Memorial Hospital; recording secretary, Mrs. Jane Barker Homer; treasurer, Miss Esther Dart of the Stillman Infirmary, and corresponding secretary, Miss Charlotte W. Dana of the Boston Lying-in Hospital.

The officers elected by the State League of Nursing Education were the following:—

President, Miss Emma E. Nichols, Boston City Hospital; vice president, Miss Bertha Allen, Newton Hospital; secretary and treasurer, Mrs. Alice H. Flash, Massachusetts Homeopathic Hospital.

In the evening was held the second annual dinner of the Massachusetts Red Cross Nurses under the presidency of Dr. Laura A. C. Hughes. The speakers at this dinner were Surgeon General Frank P. Williams, representing Governor Walsh; Mgr. Splaine; Emergency Secretary Louisa Loring of the Massachusetts Red Cross, Miss Catherine P. Loring, and Miss Mabelle Welch, night superintendent of nurses at the Peter Bent Brigham Hospital, who recently returned from six months' service at the Red Cross hospital at Paignton, South Devon, England.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending June 9, 1915: Diphtheria, 77 cases, of which four were non-resident; scarlatina, 120 cases, of which 18 were non-resident; typhoid fever,

seven cases; measles, 236 cases, of which two were non-resident; tuberculosis, 66 cases, of which four were non-resident.

The death rate of the reported deaths for the week was 15.11.

Massachusetts Medical Society.

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY.

MEMORIAL RESOLUTION FOR DR. KELLY.—Whereas, God in his infinite wisdom has seen fit to end the earthly life of our former president, Seth Wight Kelly of Woburn:

Resolved: That the members of this Society deeply deplore the loss of their highly esteemed fellow member, who was one of the early members of this Society, always interested and faithful to its obligations and so adding greatly to its efficiency and success. We wish to express our heartfelt appreciation of his efforts and of his many virtues. He was a gentleman of the old school in ideals and a true New Englander of the finest type. As a physician he was learned, proficient, honored and beloved.

Resolved: That a copy of these resolutions be sent to his bereaved family, another to the BOSTON MEDICAL AND SURGICAL JOURNAL, and another be spread on the records of our district society.

Miscellany.

THE CULTIVATION OF DRUG PLANTS IN THE UNITED STATES.

In a recent bulletin (No. 663), "Drug Plants Under Cultivation," the United States Department of Agriculture warns farmers that in order to have the cultivation of drug plants financially successful in this country, the introduction of improved methods and the extensive use of machinery is probably necessary. Under these circumstances the natural tendency will be to increase the production in the interest of economy. The demand for many drug plants, however, is so limited that if large areas are brought under cultivation there is considerable danger of overproduction. Prospective growers are urged, therefore, to acquaint themselves with market conditions before investing any considerable sum of money in this way.

On the other hand, the number of drug plants which may be grown in the United States is large. Many native medicinal plants which are found in their wild state in a few sections have been successfully cultivated in situations far beyond their natural range. In suit-

able soil and under favorable weather conditions the following plants have done well under cultivation in numerous places in the Central and Eastern states and, if the difference in climatic conditions is not too great, will probably be suitable in other regions: anise, belladonna, burdock, caraway, catnip, camomile, conium, coriander, digitalis, dill, echinacea, elecampane, fennel, henbane, horehound, pennyroyal, sage, stramonium, tansy, thyme.

The bulletin already mentioned contains specific instructions for the cultivation of each of these plants and of a number of others. In general, it may be said that wild medicinal plants are much more difficult to propagate from seeds than species commonly grown in gardens. Moreover, in growing medicinal plants from seed it is much better to start the plants in a greenhouse or hotbed than to sow the seed directly in the field. Under any circumstances, the preparation of the soil is of prime importance. A seed bed prepared by thoroughly mixing equal parts of garden soil, leaf mold, well rotted manure, and clean sand will be suitable for the germination of most seed. The heavier the soil the greater the quantity of seed should be.

Drug plants grown for their roots are usually harvested in the fall or early in the spring, while the plant is still dormant. Roots collected during the growing season often shrink excessively in drying, which in all cases must be thoroughly done. Large roots are usually split or sliced, spread in thin layers on clean floors, and stirred or turned frequently. The process of drying may take several weeks, although the time can be reduced by the use of artificial heat. Good ventilation is an essential in order that the moisture driven off from the roots may be allowed to escape.

Leaves and herbs are usually harvested when the plants are in flower. Picking by hand in the field is a slow process, and the entire plant is, therefore, often cut and the leaves stripped after the plants have been brought in. Flowers may be gathered either by hand, which is a laborious method, or by devices similar to a cranberry scoop or a seed stripper.

In addition to the care and knowledge needed for the production of these medicinal plants, the grower must be familiar with market conditions. In many cases there is no local market for the product, and the grower should then send samples to dealers in crude drugs or the manufacturers of medicinal preparations in order to obtain a price for his crop. Some growers who have been careful to maintain a very high quality in their product have succeeded in building up a trade at a price a little above the prevailing market quotations. It is also possible to secure a contract for the sale of the entire crop in advance, thus insuring a definite market. In general, the bulletin says, the growing of drug plants in this country seems to be more suitable to well equipped cultivators who devote them-

selves entirely to it than to the general farmer who looks upon it only as a minor source of income.

Correspondence.

THE CLEAN MILK BILL.

CITY HALL, WEST NEWTON, JUNE 4, 1915.

Mr. Editor: I have been much interested in the correspondence in regard to the so-called Clean Milk Bill and the comments thereon which have appeared in the JOURNAL and I cannot see that the veto of the bill has been such a blow to the cause of clean milk.

It has always seemed to me that bill was unnecessary, for Chapter 744 of the Acts of 1914 gives local boards of health all the power needed to insure clean milk: if the local boards do not choose to exercise that power it is their own fault or that of the communities which they serve.

Under the provisions of Chapter 744 no one, be he producer, contractor or storekeeper, can sell milk in any city or town in Massachusetts until every dairy from which the milk is derived has been granted by the local board of health, a permit stating that it conforms to local requirements.

The Attorney-General has ruled that the local board is the sole judge as to whether it will or will not issue this permit. Further than this the local board has the power to revoke any permit once granted if, in its opinion, the conditions under which it was issued have been violated. If a permit is revoked a notice must be sent to the State Department of Health, which in turn must notify other communities of the fact.

As Dr. Luce truly says in his letter in the JOURNAL of June 3d, a dairyman will very quickly clean up if he finds that he is going to lose his market for his product.

As for the experience of the Winthrop Board of Health, referred to in another article, it could have asked the contractor to specify which of his 1500 dairies he would use for supplying Winthrop. Having this list, the dairies on it could be inspected and, as by local ordinance, a dealer can be prohibited from changing his source of supply without previously notifying the local board, the situation would be under control. If he refused to give this list his permit for selling any milk in Winthrop could have been revoked. While this would perhaps have been an extreme measure, it was entirely within the power of the board, as I understand the law.

It is difficult for the board of a small community to do out of state inspection and this branch of the work might well be delegated to the State Department of Health, but within the state the local boards should control the work.

Where milk comes into two or more neighboring communities from the same districts these communities can pool their issues, the inspector of one doing the work for both in a given section, thus preventing duplication. Each community could appoint the inspector of the other its inspector for this work.

In closing permit me to say that when the public comes to realize that clean milk deserves a higher price than ordinary milk and is willing to pay for it, the producer will have more encouragement to give it what it wishes.

At present the man who tries to live up to requirements and produce clean milk sees his neighbor who has a dirty dairy get the same price for his dirty milk that he does for his clean milk. Naturally he becomes discouraged and ceases to care.

FRANCIS GEO. CURTIS, M.D.,
Chairman, Newton Board of Health

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING JUNE 5, 1915.

CONTRIBUTIONS.

Dr. Arthur G. Larkin, New York, N. Y.....	\$ 10.00

NOTICES.

THE PSYCHOPATHIC HOSPITAL, 74 Fenwood Road, Boston. Third annual conference on the Medical and Social Work of the Psychopathic Hospital, Boston, Friday, June 19, 1915, 4 to 6 P.M., under the auspices of the Trustees of the Boston State Hospital.

(Chestnut Hill or South Huntington Avenue cars—alight at Fenwood Road.)

Program 4 to 6 P.M. President Henry Lefavour, Chairman of the Board of Trustees, will preside.

1. "The Intensive Group of Psychopathic Social Service Cases," Mary C. Jarrett.

2. "Routine Mental Tests as the Proper Basis of Practical Measures in Social Service," Helen M. Wright.

3. "Conclusions from Repeated Mental Tests of Certain Psychopathic Subjects," J. H. Beasley.

4. "The Multiple Choice Method of Mental Examination in Estimating Candidates for Employment," C. Rossy.

5. "Problems Suggested for a Review of Faradic Sensory Threshold Work with Psychopathic Subjects," G. Philip Grabfield.

6. "Analysis of Recoveries at the Psychopathic Hospital: III. A Third Series of One Hundred Cases, Considered Especially from the After-Care Standpoint," Frankwood E. Williams.

7. "Massage in Hypertensive and Hypotensive Cases," J. P. Krasnye.

8. "Spinal Fluid Sugar in Psychopathic Subjects," H. C. Solomon and J. B. Rieger.

9. (Presented in brief abstract.) "Gold Sol Reaction."

(a) "The Clinical Status of the Method: Spinal Fluid Determinations in 500 Cases," H. C. Solomon.

(b) "Is the Cerebrospinal Syphilis Gold Sol Reaction in Some Sense a *Forme Fruste* of the Paretic Reaction?"

(c) "The Bacteriology and the Gold Sol Reaction of Post-Mortem Cerebrospinal Fluids," Myrtelle M. Canavan and E. S. Welles.

(d) "Gold Sol Reactions in Miscellaneous Body Fluids," E. S. Welles.

10. "The Margin of Error in Psychopathic Hospital Diagnoses: Second Study, 1914," E. E. Southard.

The following are presented by title or in the form of exhibits or charts, on view in the out-patient department and in the laboratories, 3 to 4 P.M.

11. "Variations in the Sensory Faradic Threshold of Psychopathic Subjects: Fifth Study—Psychoneuroses," G. Philip Grabfield.

12. "Effects of Treatment of Alcoholic Conditions at the Psychopathic Hospital and at General Hospitals," Donald Gregg.

13. "Photographs and Specimens from a Tumor of the Basis Cerebri," Donald J. MacPherson.

14. "Fatty Changes in Purkinje Cells of Cerebellum in Toxic Psychoses," Egbert W. Fell.

15. Note on the Frequency of Surgical Conditions and Operations in Hysterical Subjects," A. G. Gould.

NOTE.—The Out-Patient Department and the Laboratories will be open for inspection before the meeting, 3 to 4 P.M., and will contain certain exhibits and demonstrations.

The more social part of the program has been put before the more medical part for the benefit of those who come with special interests but limited time.

HARVARD MEDICAL ALUMNI ASSOCIATION.

An informal table d'hôte luncheon will be held by the Harvard Medical Alumni Association on June 23 at the University Club in San Francisco. Dr. William P. Lucas of the University of California Medical School and Mr. William Thomas, president of the San Francisco Harvard Club will be in charge.

APPOINTMENTS.

BOSTON MILK AND BABY HYGIENE ASSOCIATION.—

At a meeting of the trustees of the Boston Milk and Baby Hygiene Association on June 2, Dr. J. Herbert Young of Newton, Mass., was unanimously appointed medical director to succeed Dr. Arthur A. Howard of Boston who has recently resigned.

JOHNS HOPKINS HOSPITAL.—Dr. Roscoe W. Hall has been appointed resident physician of the Phipps Clinic of the Johns Hopkins Hospital, in succession to Dr. David K. Henderson who has been appointed superintendent of the Royal Asylum at Glasgow, Scotland.

STANFORD UNIVERSITY MEDICAL SCHOOL.—Dr. Charles Harvey Bailey has been appointed assistant professor of pathology. Dr. Henry Augustus Stephenson, assistant professor of obstetrics and gynecology. Dr. George DeForest Barnett instructor in medicine and Dr. Jean Redman Oliver instructor in pathology.

UNIVERSITY OF CALIFORNIA.—Dr. Henry Albert Mattill has recently been appointed assistant professor of nutrition.

UNIVERSITY OF SHEFFIELD.—Dr. J. Sholto C. Douglas, formerly lecturer on pathology in the University of Manchester, England, has been appointed Joseph Hunter professor of pathology in the University of Sheffield.

RECENT DEATH.

DR. JOHN HILDRETH MCCOLLOM, formerly superintendent of the Boston City Hospital, died at his home, 29 Ivy Street, Boston, June 14, aged 72 years. He joined The Massachusetts Medical Society in 1869.

WATER DRINKING.*

WHEN SHALL WE DRINK WATER?

MAY WE TAKE IT WITH MEALS?

BY ELBRIDGE G. CUTLER, M.D., BOSTON.

It seems hardly necessary to propose the above questions before the members of this society, but as I have encountered even recently so much confusion on these points, I am glad of the opportunity to speak through you to a wider audience.

Let me begin by recalling a few postulates which we all accept:

Water is a prime necessity of life.

It enters into the human food so largely that it is estimated that fully five-sixths of the food is water in its simple form or partly in chemical combinations.

The human body likewise consists of water in about the proportion of two-thirds of its weight, so that a 150-pound man is 100 pounds water and 50 pounds solid substance. Taking the different portions of the body, it is striking to find that *muscle*, which accomplishes so much physical work, is 75% water; the *brain*, the chief director of the body forces, is 85 to 90% water; the *blood*, source of all nutrition, is over 90% water; while *bone*, whose tensile strength is more powerful than ordinary pine lumber, may con-

tain over 40% of water; and finally, *saliva*, which is able to convert the starch of cereals, vegetables, and fruits into maltose, contains 99.5% of water, and its efficiency is further increased by further dilution.

In the human organism water is essential to digestion, assimilation, metabolism and reproduction. In fact, no vital process occurs in the absence of water, nor can life be long maintained without a continuance of its supply.

These truths have, most of them, been well recognized by physicians for years and they have encouraged the free drinking of water, but not at the best time. Mankind, when following the normal inclination, takes enough water to quench the natural thirst and at the time most convenient, which is usually at the meals.

Though many persons are accustomed to drink considerable quantities of water with their meals with no apparent ill effects, the statement has been, and still continues to be, made that water drunk with meals is injurious. This assertion appears to have rested solely on a priori reasoning, and not on experiment, and it is the common belief of many of the medical profession today as it is of the general public. It is commonly stated that water should never be drunk with meals, but an hour after the meal has been eaten. It is stated that water drunk while eating "artificially moistens the food, thus hindering the normal and healthful flow of saliva and the other digestive juices; secondly, it dilutes the various juices to an abnormal extent; and thirdly, it washes the food elements through the stomach and into the intestines before they have had time to become thoroughly liquefied and

*Read before the Boston Society for Medical Improvement, March 22, 1915.

digested. The effects of this upon the welfare of the whole organism can only be described as direful." (Carrington, 1908¹.) There is no proof that such effects follow the drinking of water with meals, and on the other hand, certain experiments show absolutely that these effects do not follow.

Let us consider the effects on the different secretions of drinking freely of water with meals.

One of the first to attack this question experimentally was Paul Leconte,² working in the laboratory of biological chemistry at the Institut Carnot, at Louvain. Though Colin had determined in 1884 that water taken during digestion in the horse did not disturb the normal course in the least, Leconte found that in the dog, water taken in the course of digestion was quite inoffensive and he assumed that it would be found so in the human subject.

The man, however, who has made the subject of water drinking peculiarly his own through his numerous experiments and published papers is Philip B. Hawk of Philadelphia, professor of biological chemistry in the University of Pennsylvania, and it is to him that constant reference is made in this paper. Indeed, as you will see later, the communication is essentially a presentation of his views.

Saliva. All agree that water should not be used to moisten the food in the mouth. This should be accomplished by proper mastication and the natural insalivation which follows in the healthy subject. No water should be taken into the mouth till this chewing, insalivation and swallowing have been accomplished. Taken in this way, water has no effect on the secretion of saliva.

Gastric Juice. Pavlov,³ experimenting on dogs with divided vagi, showed that water stimulates the flow of gastric juice if comparatively large amounts—400-500 c.c.—are ingested, but that with small amounts—100-150 c.c.—in half the cases observed, not the least trace of secretion could be found. Only prolonged and widely spread contact of the water with the gastric mucous membrane gave a constant and positive result. Since the vagi were divided, the effect of the water must have been that of a chemical excitant.

Foster and Lambert⁴ in experiments on the influence of water when taken with food, showed that water causes not only a more voluminous secretion, but also a more acid secretion.

Bergem, Rehfuss and Hawk⁵ find as follows:

1. Water, either cold—10.5° C.—or warm—50° C.—is a very strong gastric stimulant.
2. In the average normal individual, water produces fully as great a stimulation (as measured by acidity and enzyme values) as does an Ewald test meal, and the acidity follows a similar type of curve. A simple water meal might, therefore, be substituted in many instances for the Ewald meal, and has the additional advantage of demonstrating any food remnants.

Bile and Pancreatic Juice. Pavlov⁶ proved that water acts as an excitant of the pancreatic juice. When 150 c.c. of water is introduced into the stomach of a dog, the pancreas begins to secrete, or its flow increases, within a few minutes after the water has entered the stomach. Since this amount of water is insufficient to excite the flow of gastric juice, the secretion of pancreatic juice is not secondary to a secretion of the gastric juice, but is a direct result of the presence of water in the stomach.

In dogs with pancreatic fistulae, it has been shown that following chemical and psychical stimuli, there is a parallelism between the secretion of gastric juice and pancreatic juice. All kinds of acids are powerful excitants of pancreatic secretion. Large amounts of acid chyme pouring into the small intestine cause increased pancreatic secretion with increased flow of pancreatic juice. It has been shown that the biliary secretion is also increased, thus augmenting the digestive properties. Thus the increased acidity of the gastric contents resulting from the stimulating action of water causes a far more active digestive juice to be poured out upon the chyme when it reaches the intestine. Further, Hawk⁷ has shown increased pancreatic activity to follow water drinking with meals, the index being the output of fecal amylase.

Intestinal Juice. Under ordinary circumstances the intestinal juice is secreted only by those portions of the intestines with which the food is in contact (Hawk). Mechanical stimulation produces a secretion which is shown to be comparatively poor in enzymes and contains largely salt and water. When poured out upon food the intestinal juice is rich in enterokinase, but the pancreatic enzymes are even greater stimuli than food in this respect (Hawk).

The Effect of Dilution upon Enzyme Activity. Hawk points out that enzyme reactions, like other chemical reactions, are reversible. They do not proceed to completion unless the products of the reaction are removed as soon as formed. In a concentrated solution, the point at which the reaction comes to a standstill is reached sooner than in a dilute one, and in many instances the equilibrium of a reaction mixture may be disturbed by dilution; the reaction is forced toward completion if water is added. In the light of this fact the increased activity of gastric juice that has been observed under the influence of water may be due to the effect of dilution fully as much as to the increased acidity that accompanies it (Hawk).

The Rapidity of the Passage of Food as Affected by Water. VonMering's⁸ experiments show that as soon as water is introduced into the stomach, it begins to pass into the intestine, being forced out in a series of spurts by the contractions of the stomach. Within a comparatively short time, practically all the water can be recovered in this way through an artificial duodenal fistula, none or very little having been

absorbed in the stomach. For example, in a large dog with a fistula in the duodenum, 500 c.c. of water were given through the mouth. Within 25 minutes, 495 c.c. had been forced out of the stomach through the duodenal fistula. This result is not true for all liquids; alcohol, for example, is absorbed readily.

Hawk,⁹ in a series of beautiful and convincing experiments, arrived at the conclusion that copious water drinking caused an increased excretion of nitrogen and phosphorus in the urine. The increase in the amount of nitrogen eliminated is due, *primarily*, to the washing out from the tissues of the urea previously formed, but which has not been removed in the normal processes, and secondarily, to a stimulation of the proteid catabolism.

The increase in the excretion of phosphorus is due to increased cellular activity and the accompanying catabolism of nucleins, lecithins, and other phosphorus-containing bodies.

Strauss¹⁰ says that increased supply of liquids increases the excretion of the products of protein metabolism, but does not hasten the metabolism itself. The excretion of liquids is accompanied by loss of body weight dependent on removal of nitrogen waste, but not on loss of fat.

Fowler and Hawk,¹¹ in continuation of the studies on water drinking, investigated in the human subject the effect of the copious ingestion of water *with meals*. The subject of the experiment was placed on a normal, constant diet, and by means of a preliminary period of sufficient length, was brought to a condition of approximate nitrogen equilibrium. At this point 1000 cubic centimeters of water were added to each meal and continued thus through a period of five days. Immediately following this period came a final period of eight days, during which the original normal constant diet was again maintained and the after-effects of the copious water ingestion observed.

In view of their experiments, they regard the current statements respecting the exceedingly harmful influence of water drinking with meals as misleading, and arrive at the following conclusions:—

The daily drinking of three litres of water *with meals*, for a period of five days, by a man twenty-two years of age, who was in a condition of nitrogen equilibrium through the ingestion of a uniform diet, produced the following findings:—

1. An increase in body weight, aggregating two pounds in five days.

2. An increased secretion of urinary nitrogen; the excess nitrogen being mainly in the form of urea, ammonia, and creatine.

3. A decreased excretion of creatinine and the coincident appearance of creatine in the urine. The decreased creatinine output is believed to indicate that the copious water drinking has stimulated protein catabolism. The appearance of creatine is considered evidence that

the water has caused a *partial* muscular disintegration resulting in the release of creatine, but not profound enough to yield the total nitrogen content of the muscle. The output of creatine is, therefore, out of all proportion to the increase of the excretion of total nitrogen.

4. An increased output of ammonia, which is interpreted as indicating an increased output of gastric juice.

5. A decreased excretion of feces and of fecal nitrogen, the decrease in the excretion of fecal nitrogen being of sufficient magnitude to secure a lowered excretion of both the bacterial and the non-bacterial nitrogen.

6. A decrease in the quantity of bacteria excreted daily.

7. An increase in the percentage of total nitrogen appearing as bacterial nitrogen.

8. A lower creatinine coefficient.

9. A more economical utilization of the protein constituents of the diet.

10. The general conclusion to be reached as the result of this experiment is to the effect that the drinking of a large amount of water with meals was attended by many desirable and by no undesirable features.

J. B. Orr,¹² in a series of experiments on humans, gives the following summary. The excessive ingestion of water produces:—

1. An increased excretion of urinary nitrogen, which is most marked on a low protein diet.

2. A retention of nitrogen on the return to normal consumption of water in the case of excessive protein intake.

3. An increase in the percentage of total nitrogen excreted as urea.

4. A marked increase in the excretion of ammonia.

5. No excretion of creatine and no decrease in the excretion of creatinine.

6. A decrease in the fecal nitrogen, which is interpreted as indicating a more complete utilization of the food protein.

It is suggested that the results indicate that the influence of the increased water consumption is to accelerate both the catabolic and the anabolic phases of protein metabolism.

Hawk¹³ showed that when water drinking accompanies the taking of food, the passage of water is delayed somewhat. His experiments showed that the equivalents of from one-half to three-quarters of the amount of water ingested during a meal, if this amount was large, may be voided in the urine within 45 to 90 minutes thereafter. That the food elements were not thereby washed through the stomach into the intestine was shown by Cohnheim.¹⁴ Along the smaller curvature there is formed a trough connecting the antrum pylori with the cardiac opening, and through this water flows past the bolus of food lying in the stomach without washing any of the exterior away. Even when digestion is at its height, and when gastric juice is being

secreted in large amounts, almost neutral water is often found leaving the stomach. Cohnheim also states that there is no dilution of the stomach contents by liquid food, and the accurate regulation of the pyloric sphincter is not disturbed whether water is taken with the meal or not.

From this brief review of the facts regarding the drinking of water with meals, we may say:

1. The ingestion of large amounts of water with meals not only does not inhibit the normal flow of digestive juices, but acts as an excitant to their flow.
2. The digestive juices are not rendered less efficient by dilution, but on the contrary, enzyme action is more complete, within limits, the greater the dilution.
3. Even if the food were washed into the intestine more rapidly than usual, contrary to Cohnheim's belief, the greater efficiency and greater amount of the digestive juices would outbalance this.

Hawk¹⁵ carried on some other experiments on men living on a uniform diet to determine the utilization of ingested fat under the influence of copious and moderate water-drinking with meals. He found that when one liter of water additional was taken with meals, the average daily excretion of fat in the feces was much reduced below that found when a minimum amount of water was taken with meals; one and one-third liters had a like effect; a similar but less marked reduction was observed when 500 c.c. of water were taken with meals.

The decreased excretion of fat observed during water drinking with meals was usually evident for a number of days after water had ceased to be taken in large or moderate amounts with meals, indicating that the beneficial influence of water was not temporary but was more or less permanent.

A slight gain in weight accompanied the water drinking, and this gain was not subsequently lost.

After several months of moderate water drinking with meals, a pronounced improvement in the digestibility of fat was observed, the percentage utilization having risen from 94.3 to 96.5.

The better digestion and absorption of fat was probably due to the following factors:

1. Increased secretion of gastric juice and independently of pancreatic juice as a result of the stimulating action of water.
2. Increased acidity of the chyme, bringing about a more active secretion of pancreatic juice and bile.
3. Increased peristalsis, due to larger volume of material in the intestine, and increased blood pressure due to rapidly absorbed water.
4. A more complete hydrolysis of the fats by lipase, due to increased dilution of the medium and consequent more rapid absorption.

Hawk¹⁶ in another paper gives the results of his investigations on the utilization of ingested protein under the influence of copious and moderate water drinking with meals.

He found that the ingestion of large amounts (1000 c.c.) of water with meals caused the protein constituents of the food to be more completely utilized, as shown by a decrease in all forms of nitrogen in the feces. When 500 c.c. were taken with meals, no significant changes in protein utilization could be observed, as there were in fat and carbohydrate; the protein data do, however, permit of the negative conclusion, that absolutely no undesirable effects were to be observed as the result of the ingestion of 500 c.c. of water with the meals. Even when over two liters of water were taken daily, with the meals, there was no indication of untoward effects as a result.

As before, the beneficial results of water ingestion with meals were not transitory, but were more or less permanent, extending beyond the time of the experimental period.

A tenth paper by Hawk on the fecal output and its carbohydrate content under the influence of copious and moderate water drinking with meals, ends with the following conclusions:—

1. In men living on a uniform diet the addition of 1000 c.c. of water to each meal causes a decrease in the excretion of fecal material, both dry matter and moisture.
2. Under the same conditions a decrease in excreted carbohydrate material was also observed.
3. The better utilization of food material thus evident was not temporary, but appeared to extend for some time following the use of water.
4. The ingestion of a smaller amount of water (500 c.c.) and the use of a large volume of water (1333 c.c.) by one accustomed to drinking water with meals showed a similar but less marked reduction in the excretion of carbohydrate.
6. The beneficial effects noted are probably due to the stimulatory action of water upon the digestive secretions, to the increased dilution which facilitates enzyme action and materially aids in absorption, and to a conservation of the intestinal energy involved in the secretion of a diluting fluid which is necessary when insufficient water is ingested.
8. Many desirable and no undesirable effects were obtained by the use of water with meals, and, in general, the more water taken the more pronounced were the benefits.

These laboratory findings are entirely corroborative of the observation of the writer that abundant water drinking during meals promotes rather than impairs health. Brought up in the country in the same house with several boys and girls, the writer was allowed and even encouraged to drink abundantly of water at each of

the meals, especially as the water supply was supposed to be uncommonly good. As children we were never ill, and all have carried the water drinking habit through life. The writer ever since he can remember has taken from two to six tumblers of water at each meal, and has had perfect health throughout his whole life. On first hearing that water should be taken between meals to insure good health, a little reflection convinced him that the rule could not be universal, for here was he and his early companions living examples to the contrary. He, therefore, not only made no change in his own habits, but encouraged others to do as he did, and later in life so advised his patients. The reasoning was as follows: the gastric juice, bile, pancreatic juice, and intestinal juices necessary for digestion are supplied as fluids derived from the secreting cells of the respective glands. The secreting cells obtain their supply from the liquid portions of the blood, which in turn is kept in proper bulk by the absorption of water wherever it can be obtained. It would seem to be more natural to seek its supply through the intestines at the time of digestion, and therefore the taking of water with meals, since it satisfied a natural desire and, moreover, was productive of a sense of well-being, was to be commended.

The observation was made that children and untutored people ate and drank at the same time, not only without harm but apparently with benefit.

In conclusion, therefore, we may say as the result of clinical observation, supported by laboratory research, that it is advisable for people in ordinary health to drink water as desired with meals, or to the extent of from 2 to 4 or more tumblers at each repast, and that we may expect a continuance of good health in so doing, or an improvement even, provided that the food taken be first thoroughly masticated and insalivated and then swallowed, and that the water be then ingested.

THE STARVATION METHOD VERSUS GRADUAL CARBOHYDRATE REDUCTION AS A TIME SAVER IN THE TREATMENT OF DIABETES.

BY HENRY A. CHRISTIAN, M.D., BOSTON.

[From the Medical Clinic of the Peter Bent Brigham Hospital.]

A LARGE proportion of the diabetic patients coming to our hospitals are wage earners or housewives, only in part incapacitated for their regular duties. A small proportion are advanced cases no longer able to work. To the former, days saved in their treatment are of very great importance. Incidentally days saved in treatment are economies in hospital administration, which allow the benefits of the institution to be bestowed upon more individuals per annum. In both ways there is a marked gain in shortening the time required for treatment in any disease. With these facts in mind let us examine our methods of managing diabetes from the point of view of time.

Today in treating a diabetic we seek first to grade the case according to severity, second to get the patient's urine sugar-free, and third to establish his limits of tolerance to glucose-producing foods and so far as possible to increase this tolerance, and in doing this we desire to avoid risks to the patient and to maintain the patient in as good a state of strength and comfort as possible. For the first we find out the patient's excretion of glucose and acetone bodies when ingesting some standard diet containing known amounts of protein, carbohydrate and fat. Usually such a diet contains about 100 gms. of protein and 55 gms. of carbohydrate.

To get the patient sugar-free the method followed until recently has been the gradual reduction of the carbohydrates of the diet. Lately, following the investigations of Allen,¹ diabetic patients have been starved until they are sugar-free. Starvation has been complete in some cases; in others thrice boiled green vegetables² have been given. At times alcohol has been allowed to supply some calories during the period in which the patients were being starved.

To establish the limits of tolerance, to the diets of sugar-free patients gradually are added known amounts of carbohydrate and protein; the amount being determined by the continuance or not of the absence from the urine of glucose.

Without attempting to discuss the theories underlying metabolism in diabetes, the time element in getting the patient sugar-free by each of these two methods will be illustrated by consequent

¹ Allen, F. M.: The Treatment of Diabetes. *Boston Med. and Surg. Jour.*, 1915, Vol. clxvii, p. 241.

² The vegetables are boiled through three waters, the water away all the water. Nearly all starch is thus removed, and the most severe cases generally take these thrice-boiled vegetables gladly and without glycosuria.

tive cases admitted to the Peter Bent Brigham Hospital. The earlier cases were treated by a gradual reduction in the carbohydrate intake; the later by Allen's starvation method. In each method the first two or three days were used in grading the severity of the case by studying the excretion in relation to a standard diet. Though taken in succession, none of these cases happened to be of the type grouped as severe. In fact, the figures given show the results of treatment only in mild or moderately severe diabetics.

In Chart I appears the approximate duration of the symptoms of the disease and the day on which the patient got sugar-free.

* Starved as soon as admitted to the hospital.

Of our series of recent diabetics the average duration of the treatment by the gradual reduction of the carbohydrate intake was for these patients 8.9 days between the time of admission and the first day on which the patient's urine was sugar-free. By the starvation method the

average for the same thing was 3.2 days, which time includes in all except one case, one or two days of a diet given with the view of standardizing the severity of the diabetes in these cases. Had these patients been put on a starvation diet on admission then the time would have been reduced by one or two days.

Particularly interesting in this connection is a group of cases which were in the hospital more than one time and so were subjected to both methods of management. The first time carbohydrates were gradually reduced because this admission antedated the publication of Allen's method. The second admission of the patient was after we had begun to use Allen's method. Two cases were begun with the gradual reduction of the carbohydrate intake and subsequently were put upon Allen's starvation method. These cases will be briefly reviewed.

A patient (Peter Bent Brigham Hospital, Med. No. 330) was admitted to the hospital Sept. 9, 1913, giving the history of having had itching and soreness about the genitals for six weeks and for one week frequent and painful urination. By gradual reduction of carbohydrate intake she was sugar-free on the 11th day, again on the 14th day, and finally on the 25th day, after which she remained sugar-free. The amount of carbohydrate intake and the amount of glucose in the urine is shown in the accompanying chart. (Chart II.)³

This patient was readmitted to the hospital on February 3, 1915 (Peter Bent Brigham Hospital, Med. No. 2276). On this admission she was put on the Allen starvation treatment, and on the 3d day of her stay in the hospital she became sugar-free, as shown by the chart. (Chart III.)

In a similar way another patient (Peter Bent Brigham Hospital Med. No. 1230) was admitted to the hospital on May 21, 1914, giving a history that eight years previously sugar had been discovered in her urine. By the method of gradual reduction of the carbohydrate intake this patient did not become

³ In these charts the solid black columns represent carbohydrate intake in grams and the hatched columns glucose in the urine in grams.

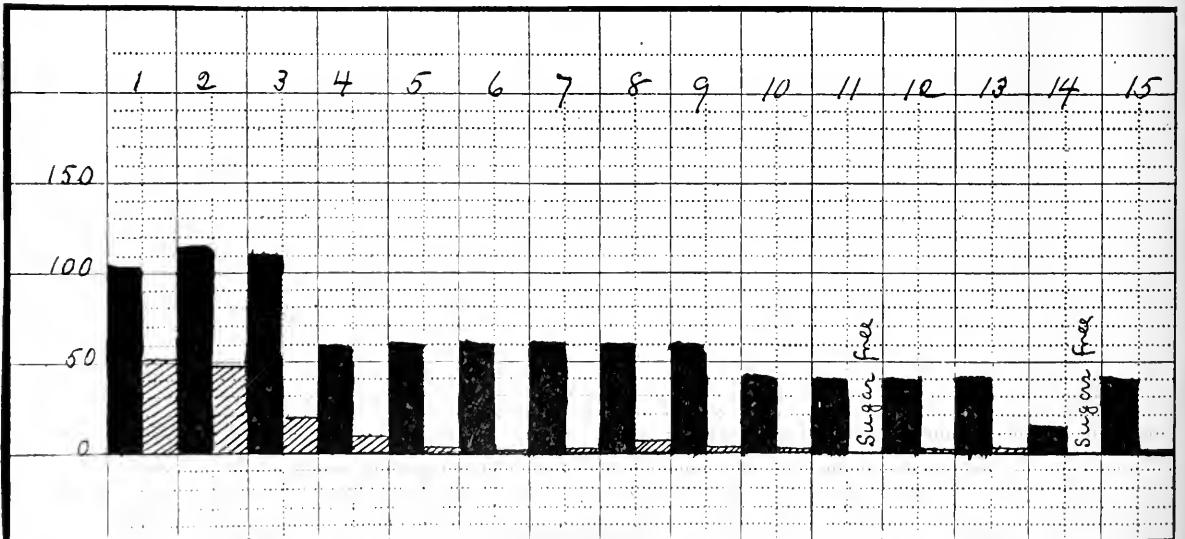

Chart II.

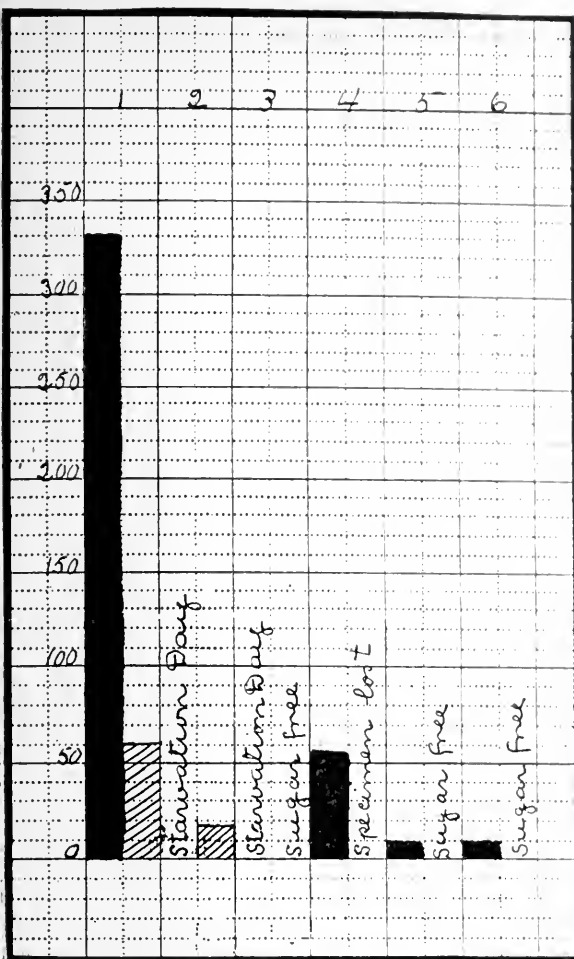

CHART III.

sugar-free until the 18th day. She was admitted to the hospital a second time (Peter Bent Brigham Hospital, Med. No. 2245) on January 29, 1915, and by the starvation method became sugar-free on the third day.

A third patient (Peter Bent Brigham Hospital, Med. No. 942) was admitted to the hospital March 12, 1914, giving the history that sugar had been found in her urine three years before admission, since which time she has been constantly annoyed with headaches, thirst, polyuria and for a somewhat longer time she has had an ulcer on the left leg. By the gradual reduction method she became sugar-free on the 15th day. (Chart IV.)

This patient was readmitted to the hospital (Peter Bent Brigham Hospital, Med. No. 2509) on March 18, 1915, and on the starvation method became sugar-free on the 3d day. (Chart V.)

The following case is of particular interest in this connection because it represents a severe case of diabetes in whom we had much difficulty getting the patient sugar-free by the ordinary method of gradual reduction of the carbohydrate intake, and who, after becoming sugar-free, repeatedly had traces of sugar on very slight carbohydrate intake, though he would get sugar-free after one, two or three ordinary green vegetable days. This patient (Peter Bent Brigham Hospital, Med. No. 1655) was admitted to the hospital on Sept. 17, 1914, with a history of having developed excessive thirst with polyuria about nine months before admission. With gradual reduction of carbohydrate intake he had become sugar-free for the first time on the 25th day, following three ordinary (not thrice boiled) green vegetable days. Sugar reappeared after two days with a very moderate carbohydrate intake. It disappeared only after a repetition of the green vegetable days. He then remained sugar-free for 11 days on a 5 gm. carbohydrate and 65-70 gm. protein intake. This took him to Oct. 30, 1914. From Oct. 30 to Nov. 4 his urine contained a trace of sugar on this same diet. This trace disappeared on Nov. 5 and remained absent until Nov. 16, when with a very slight increase in his carbohydrate intake and a slight reduction in his protein intake sugar reappeared in small quantities. This picture repeated itself until Dec. 15, when he was put on a succession of seven days of thrice-boiled vegetables with alcohol, as described by Allen. Following this, he was sugar-free for only a few days and then began to put out from 10-12 gms. of sugar per day up to Dec. 29, when, following three days of thrice-boiled vegetables and alcohol he became sugar-free

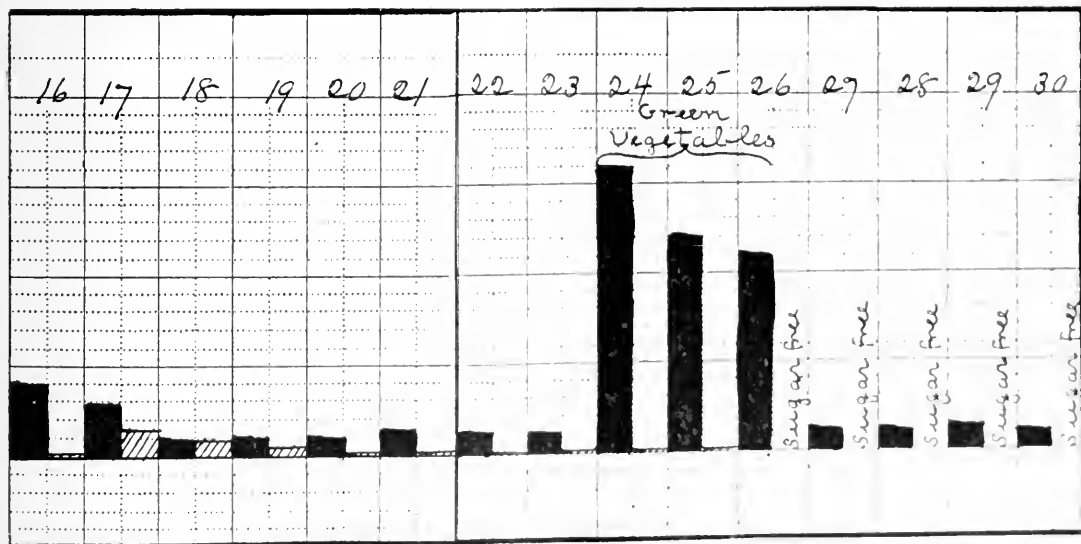

Chart II.

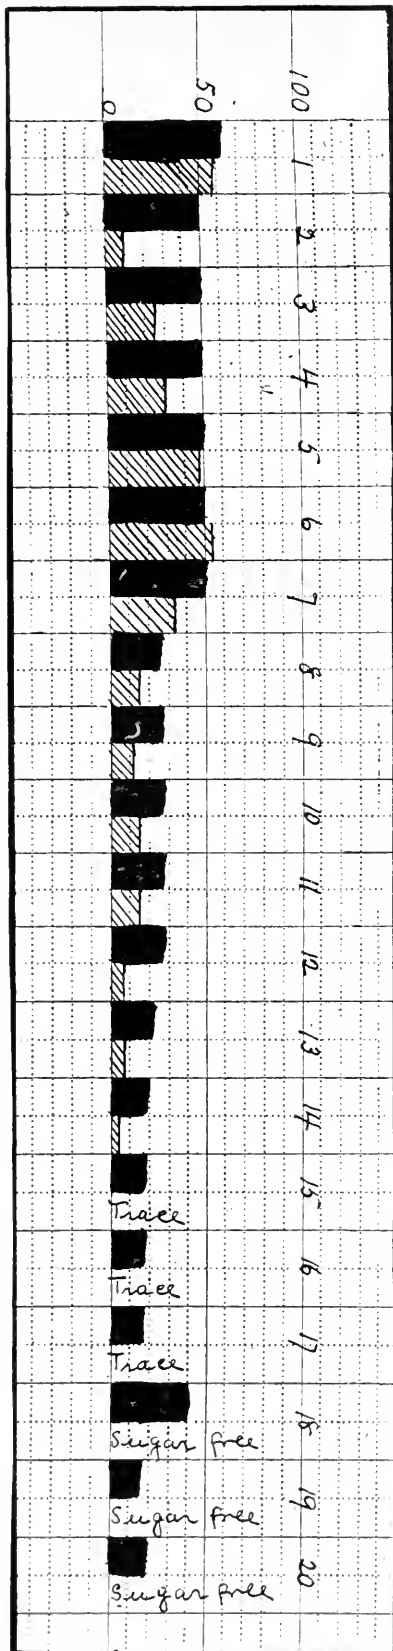

CHART IV.

and remained so until Jan. 13, when a slight amount of sugar appeared in his urine following a slight increase in his diet. This patient's weight chart was of much interest as he gained weight steadily on his reduced diet, and only remained sugar-free when his caloric intake was so reduced following starvation days that his weight made only slight gains.

Somewhat similar is the following patient (Peter Bent Brigham Hospital, Med. No. 1963) who was admitted to the Hospital Nov. 27, 1914, with a history of polyuria beginning four or five days before admission. On a gradual reduction of carbohydrate intake, this patient was still putting out sugar in his urine 17 days after admission on a diet of 10 gms. of carbohydrate, and 50-60 gms. of protein. He was then given a day on which he had only thrice-boiled vegetables and alcohol. On the second day of this he became sugar-free. However, he was kept on this diet for four days, but when he was returned to a 10 gm. carbohydrate and 90 gm. protein diet sugar reappeared, but promptly disappeared on a repetition of the thrice-boiled vegetable days. Subsequent to this he remained sugar-free on a 10 gm. carbohydrate and 60 gm. protein diet and established some tolerance, so that he eventually was sugar-free on a diet of 30 gms. of carbohydrate and 80 gms. of protein.

In all of these cases fluid, carbohydrate and protein intake were charted in relation to output; the patient's weight was noted; the caloric intake; acetone, diacetic acid and ammonia excretion, etc., were quantitated. However, in the present paper only the glucose excretion has been considered in relation to the time element. In Chart I it will be seen that it required of each patient, with the exception of one exceedingly mild case, a stay in the hospital of from 7 to 20 days before the urine became sugar-free when carbohydrates were gradually reduced, while by Allen's starvation method the same thing was accomplished for all except one patient in 4 days or less. The difference in results obtained from the two methods is shown especially well by the cases treated on two admissions approximately one year apart. In these three patients it required 25 days, 18 days and 15 days respectively to render them sugar-free by the method of gradual reduction of carbohydrate intake, while each was sugar-free on the third day by the Allen starvation method.

It will be seen that by this new method of managing cases of diabetes introduced by Dr. Allen the time required for rendering a patient sugar-free has been greatly shortened. It is done, too, so far as we have observed, with very slight inconvenience or discomfort to the patient. What of the third aim of a diabetic treatment, the establishment of an increased tolerance? It has seemed to us that tolerance is as rapidly acquired after the starvation method of getting the patient sugar-free as after gradual carbohydrate reduction. This being true, Dr. Allen's methods have shortened very materially the time of hospital stay required of cases of diabetes of moderate severity, and in this respect have improved

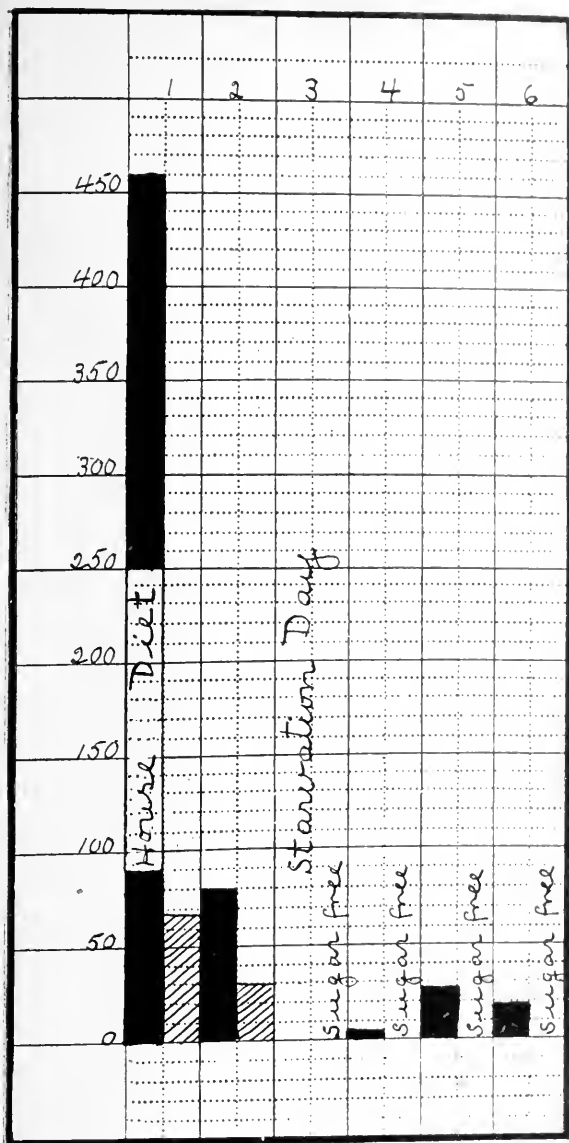

CHART V.

greatly our means of managing diabetics. Dr. Allen himself has pointed out the value of his methods in managing cases of very great severity. They seem to us to be thoroughly safe methods to apply in treating any case of diabetes.

SUMMARY.

The starvation method of Allen for rendering a diabetic sugar-free, in addition to being a safe method, has shortened very materially the time required to get a patient with diabetes sugar-free, and so permits of a large part of the patient's stay in the hospital being devoted to building up the patient's tolerance for carbohydrates. To put it another way, the method saves for the patient and for the hospital one or two weeks of time.

PSYCHOPATHIC HOSPITALS AND PROPHYLAXIS.*

By FRANKWOOD E. WILLIAMS, M.D., BOSTON.

Executive Secretary, Massachusetts Society for Mental Hygiene.

From the point of view of mental hygiene, individuals may be said to fall into one of four groups:

1. Those now sane, and who will remain sane except through the working of some exogenous factor.
2. Those now sane, but who will become insane under certain conditions.
3. Those now insane.
4. Those who have been insane but who are now recovered and returned to the community.

A fifth group might be added—those yet unborn.

A program of mental hygiene must provide adequately for each of these groups. Our present system in Massachusetts provides—but not adequately, as for instance in the case of the feeble-minded and defective delinquent—for the care of those at present suffering from mental disease, and with its social service departments and its newly organized out-patient departments, for those who have been insane but who are now recovered. But from the prophylactic point of view these two groups are of the least importance.

Providing for the care of the mentally diseased after the damage has been done, important and essential as a humanitarian measure, will have as little effect in the prevention of first attacks of insanity as providing elaborate care for patients suffering from typhoid fever would have in the prevention of an increase of typhoid fever. The field for prophylaxis lies in the first two groups—those now sane, who will remain sane except through the working of some exogenous factor; and those now sane but who will become insane under certain conditions.

There are, today, in our state hospitals approximately 14,000 patients. From a prophylactic standpoint little can be done for these. But new cases are admitted to our hospitals at the rate of about 3,000 a year. The problem is, how to prevent these 3,000 each year from becoming insane. It is too much to expect that the time will ever come when this figure will be reduced to a zero. But at the present we are doing little to impede its progress to a maximum, with the maximum not yet in sight, when we might be taking steps to reduce it to a minimum. The seeds of mental disease were sown in the

* Read before the Worcester District Medical Society, February 19, 1915.

bodies of some of this year's 3,000, ten, fifteen, twenty years ago, in the form of syphilis. These patients are lost to us. But there are young men and young women who have contracted syphilis today; there are others who will contract it tomorrow, and thus become candidates for admission. For those who will be admitted this year suffering from alcoholic psychoses nothing can now be done. But these individuals are now at the end of a road which once had a beginning, and there are others entering that road today. A healthy mentality cannot be given to the feeble-minded girls now cared for by charity organizations in maternity hospitals and nothing except lack of facilities will prevent them from becoming patients at one of the schools for the feeble-minded as soon as their health will permit. But there was a time, some fifteen or twenty years ago, when prophylactic measures—the proper segregation of their feeble-minded parents, for example—would have been effective. In the case of the yet unborn children, prophylactic measures might have been applied but a few months ago. They can still be applied to the feeble-minded girls who will otherwise come to the maternity hospitals in the next twelve months of this year, and thus would be decreased the admission rate for the feeble-minded four, five, ten, fifteen years from now. There were graduated from the high schools of the state last June many ambitious young men and women who last fall entered the universities and professional schools, and who before the school year is over will have succumbed to the strain and will have been admitted to our hospitals. Many of these came of neurotic stock, and early showed peculiarities and idiosyncrasies of temperament, emotion and mental habit that might have forewarned an alert parent or family physician. Little can now be hoped for; the damage is done. But there are others who will be graduated next June, and through lack of proper understanding of themselves, start on the self-same course.

One of the great factors impeding the progress of proper measures is the inertia due to the feeling of hopelessness and helplessness with which mental disease is regarded, and the prejudice engendered by misconceptions of the nature of mental disease. The idea of diabolical possession in the case of the insanities is no longer entertained, but the theological conception which supplanted this middle age explanation—that insanity is pure mental and moral perversion and represents the outbreak of the animal and violent elements of the fallen human soul which have culpably been permitted to get the upper hand of the higher attributes—is still too prevalent. Kindred to this is the fallacy that "once insane always insane." We must come to understand that insanity is a disease. Further, that the term represents not a disease entity, but a group of diseases. And still further, that the legal diagnosis "Insane"—and the term

insane is a legal and not a medical term—carries with it no connotation as to possible outcome. Many of the insanities are not recoverable, it is true. Others are recoverable, and it should be borne in mind that when individuals recover from such forms of mental disease and return to the community, they are as capable intellectually as before their illness.

Massachusetts is one of the few states that has upon its statute books laws providing for the temporary care and voluntary admission of patients in the early stages of mental disease. These laws are wisely conceived, capable of serving a splendid purpose, and from the prophylactic point of view mark an important advance in legislation for the insane. Statistics show, however, that outside of the metropolitan district of Boston, served by the Boston Psychopathic Hospital, these laws are but little used. In some districts this is because of lack of proper facilities in the immediate neighborhood. In others it is because of a lack of a proper understanding of the purpose, action and types of cases that are advantageously served by these laws on the part of the general practitioners. In still other communities the difficulty lies in the middle 19th century views of mental disease held by members of the legal profession occupying positions as judges. We may experience something of a shock when we learn that a neighboring state still classes the insane with the criminal and places the supervision of the state hospitals in the hands of the board of prison commissioners. But it is well to examine ourselves. In one district of this commonwealth a patient who has been examined at a state hospital and found to be suffering from a mental disease, must suffer a trip back to the city from which he came, be taken to the police station, have his name entered upon the police blotter in the manner of a criminal, and must then be paraded before the police court to permit the judge to make a diagnosis before treatment of more than a week can be vouchsafed to him as a sick man. Such archaic notions impede mightily proper progress. An individual bereft of his reason has rights as an individual that must be protected, but in protecting his rights as an individual we must not forget that he has rights as a patient, and that the hope of soon regaining his rights as an individual may largely depend upon the respect that is given, at a critical time, his rights as a patient.

These misconceptions, these prejudices, these exogenous and environmental factors, so important in the prevention of mental disease, should be materially influenced in any community by the presence of a psychopathic hospital. A psychopathic hospital, in conjunction with its other functions, should serve as a prophylactic and educational station. Standing in a community on the plane with the general hospital or other specialized hospital it emphasizes mental disease as a disease and should serve as a center

to which may come for advice and counsel those suffering from psychoneuroses and the early stages of mental disease as easily and freely, and with as little prejudice as those suffering from the early stages of tuberculosis seek out a hospital for tuberculosis; a center to which can be brought for diagnosis the supposedly backward child, before further social damage has been done; a center to which parents aware of the neurotic inheritance of their children can come for advice in their children's upbringing and protection. From its lecture platform adults should receive instruction which would lead them to a better understanding of their own complex emotions, sensations and impulses, and practicing physicians should be instructed in the significance of certain early manifestations of mental disease, that they may be as capable in diagnosing and protecting these patients as they are those manifesting the early signs and symptoms of tuberculosis or cancer. Prophylaxis is but one of the many functions of a psychopathic hospital, but its possibilities as a prophylactic and educational center should not be overlooked.

PROGRAM AND DIRECTIONS FOR THE MENTAL EXAMINATION OF ASOCIAL, PSYCHOPATHIC AND DOUBTFUL SUBJECTS.

BY ROSE S. HARDWICK, BOSTON,

Instructor in Education, Boston School of Physical Education; formerly Assistant in Psychology, Psychopathic Hospital, Boston.

(Concluded from page 930.)

CLASSIFICATION OF TESTS.

The following classifications of the tests with respect to the mental functions involved are given for convenience of reference, and not as being by any means exhaustive.

The first table shows the tests in the order in which they occur in the Point Scale, the Binet Scale, the Healy Tests, the Knox Scale, and the Miscellaneous group. After each test are indicated the principal functions involved.

In the second table the same tests are reclassified under the heads of mental functions likely to be of special interest.

TABLE 1.

(Showing principal mental functions involved in each test.)

THE YERKES-BRIDGES POINT SCALE.

1. Aesthetic judgment involving perception, association, analysis.

2. Perception, apperception, visual memory, imagination.
3. Discrimination—(a) visual, (b) and (c) kinaesthetic.
4. Auditory memory for words (digits), attention.
5. Memory, imagination, attention.
6. Auditory memory for sentences, attention.
7. Perception (visual—of things, relations, meanings), association, imagination.
8. Kinaesthetic discrimination, ideation (notion of series), attention.
9. Analysis and comparison of remembered objects, attention.
10. Ideation (association and analysis).
11. Suggestibility, visual perception, comparison.
12. Motor coördination, visual perception.
13. Association (free), vocabulary, attention.
14. Imagination and command of language forms.
15. Practical judgment involving memory and imagination.
16. Visual memory, perception, attention, motor coördination.
17. Logical judgment based on imagination, analysis and reasoning.
18. Ideation, involving vocabulary, analysis, imagination, command of language forms.
9. Ideation, involving vocabulary, memory, analysis.
20. Logical judgment based on analysis and reasoning, attention, memory.

THE BINET-SIMON SCALE.

- III 1. Information, vocabulary, motor coördination.
2 = Y 6 a.
3 = Y 4 (?).
4 = Y 7.
- IV 1. Information, vocabulary.
2. Information, vocabulary, recognition.
3 = Y 4 a.
4 = Y 3 a.
- V 1 = Y 3 b and c.
2 = Y 12 a.
3 = Y 6 b.
4. Information, ideation (notion of enumeration).
5. Analysis and constructive imagination.
- VI 1. Information, perception association ideation (notion of time).
2 = Y 10.
3. Auditory apprehension for ideas, memory, attention.
4. Information, ideation (notion of right and left).
5 = Y 1.
- VII 1. (Compare V 4.)
2 = Y 7.
3 = Y 2.
4 = Y 12 b.

5. Information, color discrimination.
- VIII 1 = Y 9.
2 = Y 5.
3. Information, verbal association, ideation (notion of time).
4. Information, ideation (notion of value).
5 = Y 4 c.
- IX 1. Information, ideation (notion of equivalents).
2 = Y 10.
3. Information, ideation (notion of time).
4. Information, verbal association, ideation (notion of time).
5 = Y 8.
- X 1. Information, recognition.
2 = Y 16.
3 = Y 4 d.
4 = Y 15.
5 = Y 14.
- XI 1 = Y 17.
2 = Y 14.
3 = Y 13.
4. Aesthetic perception.
5 = Y 18.
- XII 1 = Y 4 e.
2 = Y 19.
3 = Y 6 d.
4 = Y 11.
5. Information, memory, constructive imagination.
- XV 1 = Y 7.
2. Information, attention, mental imagery, analysis, constructive imagination.
3. Ideation, attention, association, mental imagery, analysis, constructive imagination.
4. Association, (controlled), reaction-time.
- Adult 1. Ideation, analysis, constructive imagination.
2. Ideation, analysis, constructive imagination.
3. Information, vocabulary, analysis.
4. Information, vocabulary, analysis.
5. Attention (auditory), command of language forms. apprehension, analysis.

The word "information," occurring so frequently in this table, is not intended to stress unduly the more mechanical aspects of the tests, to the obscuring of their real psychological value, but to draw attention to the dependence of these particular tests upon environment. The fact is that, while correct responses in these cases do necessitate a certain mental development, the reverse does not hold true. A child may fail completely in one or more such tests without being in the least retarded mentally, and solely on account of peculiarities of environment. Thus, from the two extremes of social privilege, institution life and homes of excep-

tional wealth, come children who know nothing of money, and who, therefore, fail on VIII 4, IX 1 and X 1. On the other hand, children of small shopkeepers acquire these notions very early. Hence it is important to keep in mind always the dependence of such tests upon environment, and the danger of resting positive conclusions upon failures therein.

THE HEALY TESTS.

1. Perception (visual—rarely kinaesthetic) of form, color, and relations of part and whole, motor coördination, attention.
- II. Same as I.
- III. Same as I except for absence of color.
- IV. Same as I except for absence of color.
- V. Analysis of a concrete situation, reasoning.
- VI. Memory (visual) for concrete situation—fullness and reliability in free recital and under questioning, suggestibility.
- VII. = Y 16.
- VIII. Memory (visual and kinaesthetic) for IX. X, XI = B XV 3 (?) arbitrary associations.
- XII. Memory (visual verbal) for connected ideas.
- XIII. Memory (auditory verbal) for connected ideas.
- XIV. Memory (auditory verbal) for arbitrarily associated ideas.
- XV. = B XV 4.
- XVI. Motor coördination (accuracy and speed), attention, fatigue.
- XVII. Motor coördination, reaction to formal education.
- XVIII and XIX. Reaction to formal education.
- XX. Affectivity, constructive imagination.
- XXI. Information, analysis, constructive imagination, sentiments.
- XXII. Information, stock of ideas, sentiments, instincts.
- XXIII. Analysis, constructive imagination.

THE KNOX SCALE.

- III 1. Information, vocabulary(?), recognition.
2 = B III 1.
3 = B III 3.
4 = B III 4.
5. Information, vocabulary.
- IV 1. Perception (visual—rarely kinaesthetic) of form and size, motor coördination, attention.
2. Visual apprehension, memory, motor coördination.
3 = B IV 3 = Y 4 a.
4 = B IV 2.
5 = B IV 1.
- V 1. Compare IV 1.
2. Compare IV 2.
3 (= B V 4?)

4 = B V 2 = Y 12 a (and copy circle).

5. Auditory apprehension for ideas, memory, attention.

VI 1. Compare IV 1.

2. Compare IV 2.

3. Visual apprehension, analysis, memory.

4 = B VI 4.

5. Information, ideation (notion of time).

6 = B VI 3. Compare K V 5.

7. Information, perception, memory.

VII 1. Compare IV 1 and 2.

2. Compare IV 1.

3. Compare VI 3.

4 = B VII 4.

5 = Y 4 b.

6. Information, memory (verbal association).

7. Perception (visual, of relations), association.

VIII 1 = H III (in 5 minutes).

2. Compare IV 2.

3 = Y 5 = B VIII 2.

4. Analysis and comparison of remembered objects, attention.

5 = B VIII 5 = Y 4 c.

6 = B VII 5.

IX 1. Compare VIII 1.

2 = H 1.

3. Compare IV 1.

MISCELLANEOUS TESTS

1. Attention, analysis, planning.

2. Attention (voluntary). This is properly an affair of visual attention, the subject actually cancelling the letters indicated, but it may be adapted to the testing of auditory attention if the examiner reads the letters aloud at a uniform rate and in a carefully monotonous voice, and requires the subject to record by a pencil stroke each time an A is pronounced. The weakness of this form of the test lies in the possibility that errors of omission and of interpolation may neutralize each other in the final count.

3. Attention (voluntary), rhythm (objective and subjective).

4. Memory (visual-kinaesthetic) for arbitrary associations.

5. Analysis, constructive imagination.

6. Analysis, reasoning, ethical judgment and discrimination, sentiments.

TABLE 2.

(Showing tests bearing upon important mental functions.)

Motor Coördination.

Coarser coördination, especially of arm muscles. B III 1, VI 3 and 4.

Finer coördinations of hand and arm muscles. Puzzles. Seguin's form-board (= K IV 1, V 1, IX 3); III (= K IX 2), II, III (= K VIII 1), IV (= K adult 3); K VI 1, VII 1 and 2, IX 1, X 1, XII 1, XIII 1 and 2, adult 1 and 2; K (cube imitation test) IV 2, V 2, VI 2, VIII 2, XI 1; K (construction-block test) VI 3, VII 3.

Drawing. Y 12 (= B V 2, and VII 4 = K V 4(?) and VII 4); Y 16 (= B X 2 = H VII); labyrinths.

Writing. Y 14 (= B X 5 and XI 2), 18 (= B XI 5).

Discrimination of weights. Y 3 b and c (= B V 1), 8 (= B IX 5).

Tapping. H XVI.

Attention.

Association tests. Y 13 (= B XI 3); B XV 4 (= H XV).

Memory tests. Y 4 (= B IV 3, VIII 5, X 3, XII 1); 6 (= B III 2, V 3, XII 3); H VI, XII, XIII.

Tests involving visualization and analysis. Y 5 (= B VIII 2), 9 (= B VIII 1), 20; B XII 5, XV 2; B XV 3 (= H XI); H IX, X.

Cancellation tests. W 26.

Counting dots. W 27; K adult 4.

Labyrinths, A and B.

Association.

Free. Y 13 (= B XI 3).

Controlled. B XV 4 (= H XV), XI 4.

Memory.

Auditory:

Digits. Y 4 (= B IV 3, VIII 5, X 3, XII 1 = K IV 3, VII 5, VIII 5, XI 2); B III 3 (= K III 3).

Sentences. Y 6 (= B III 2, V 3, XII 3).

Ideas. B VI 3 (= K VI 6); H XIII and XIV; K V 5, XI 3, XIII 3.

Visual:

Geometric figures. Y 16 (= B X 2).

Ideas (verbal). H XII.

Mixed or uncertain types:

Y 5 (= B VIII 2), 9 (= B VIII 1); H VI and VIII; K VI 3, VII 3, X 6, XI 5, adult 5 and 6.

Information.

General:

B III 1 (= K III 2), IV 1 (= K IV 5), IV 2 (= K IV 4), V 4 and VI 1, VI 4 (= K VI 4), VII 1 and 3, VII 5 (= K VIII 6), VIII 3 (= K IX 5(?); VIII 4, IX 1, IX 3 (= K IX 4), IX 4 (= K X 3), X 1, XII 5; K III 1 and 5, V 3, VI 5 and 7, VII 6, X 4 and 5, XI 6, XII 5 and 6, XIII 6.

Definitions:

Y 10 (= B VI 2, IX 2), 19 (= B XII 2 = K XIII 5(?)); B adult 3 and 4.

Comparisons:

Y 9 (= B VIII 1); K VIII 4 and XI 4.

Questions:

Y 15 (= B X 4); H XXII.

Judgment.

Y 1 (= B VI 5), 3 (= B IV 4 and V 1), 8 (= B IX 5 = K IX 6), 9 (= B VIII 1), 15 (= B X 4), 17 (= B XI 1 = K XII 2), 20; K X 2, XI 4, XII 3; B XII 5; H XXI; ethical discrimination.

Constructive Imagination.

Y 2 (= B VII 3), 7 (= B III 4 = K III 4), 14 (= B X 5 and XI 1), 18 (= XI 5), 20; B V 5, VII 2 (= K VII 7), XII 5 (= XII 4), XV 1, adult 1 and 2; H XXIII; prose completion; K adult 7.

Learning Capacity.

Ability to acquire, retain and use practical information. "Information" tests, both K and B; arithmetical tests, K; H XXII.

Ability to comprehend and to follow verbal

instructions. K V 5, VI 6 (= B VI 3), XIII 3; H XIII and XIV.

Ability to learn by imitation. K (cube imitation tests) IV 2, V 2, VI 2, VIII 2, XI 1; K (construction-block test) VI 3, VII 3; H XIV; K VII 1.

Ability to learn by experience in concrete situations. H I (= K IX 2), II, III (= K VIII 1), IV (= K adult 3); Seguin's form-board (K IV 1, V 1, IX 3); K VI 1, VII 1 and 2, IX 1, X 1, XII 1, XIII 1 and 2, adult 1 and 2. Various other tests, such as the labyrinths, may be adapted to this purpose if time is taken to repeat them. The time, and the number and character of the errors are the specially significant facts. The examiner should not rely on any mechanical interpretation of them, however. A fair time record may be made by a subject whose motor co-ordination is good, even though he repeat the same errors over and over. On the other hand, a very slow solution may be due to numerous errors, wandering attention, or careful planning.

Ability to analyze a concrete situation and to plan on the basis of that analysis. Same tests as for learning by experience; H V; labyrinths.

Affectivity.

Motor co-ordination. See tests under that head.

Reaction-time. All tests, but especially H I, II, III (= K VIII 1), IV; B XV 4 (= H XV).

Suggestibility. Y 11 (= B XII 4); H VI. It is doubtful how much significance should be attached to the first of these. The second reproduces much more nearly the conditions of everyday life in which suggestibility plays an important part.

Fatigue. (1) Tests consisting of several parts, such as Y 17 (= B XI 1); Y 20; (2) groups of similar tests, such as H III and IV; and (3) any repeated tests, such as H XVI.

Aesthetic appreciation. Y 1 (= B VI 5); B XI 4.

Reaction to the situation. Apart from the evidence gathered from specific tests, important affective characteristics may come to light incidentally, in the course of the examination. The subject's attitude at the beginning may be apprehensive, resistive, sullen, indifferent, or frankly responsive. During the interview his mood may change as regards attention, enjoyment and efficiency. He may improve in these respects, or the reverse; or, after gaining for a time, he may lose ground. Apprehensiveness may disappear quickly or slowly, may be removed by an explanation, or may vanish with fluctuating attention. Some individuals display a marked capacity for criticizing their own performance; others follow the instructions in a dull fashion, apparently indifferent to the quality of their work, while still others continually look to the examiner for approval. Some show distinct initiative, readily disposing of wraps and taking the indicated seat, co-operating in the tests, and occasionally making suggestions. Some

are self-helpful, considerate and courteous, respectful of property, whether their own or another's; while some are quite the reverse of all this. Some find more pleasure in the manual tests, and some in the mental. Finally, some appear to be destitute of ambition, whereas others take a healthy delight in achievement of any sort.

Reports of Societies

CLINICAL CONFERENCE OF THE NEUROLOGICAL INSTITUTE, NEW YORK.

REGULAR MEETING MARCH 25, 1915. DR. J. RAMSAY HUNT IN THE CHAIR.

A CASE OF BRAIN TUMOR IN THE RIGHT POST-ROLANDIC AREA.

DR. WALTER CLARK HAUPT presented from the First Division a man whose symptoms though not pathognomonic of brain tumor nor yet classic in the way in which they unfolded were nevertheless believed to indicate a rapidly developing growth in the right post-rolandic area.

The patient was a clerk 40 years old, who, previous to the present illness, had been in good health and who never had had syphilis nor had he encountered trauma. He was in good health up to one year before coming into the hospital on March 15, 1915. The initial symptom seems to have been a sensation of heaviness and pressure in the left shoulder. This was not sufficient to prompt him to consult a physician nor did it keep him from work. As the discomfort was greater before a storm he attributed it to rheumatism, particularly as the pain and discomfort occurred occasionally in the right knee and hip. In December, 1914, that is, seven or

eight months after he first complained of these symptoms, they disappeared and he considered himself quite well up till six weeks ago when there developed simultaneously, with considerable abruptness, severe frontal and occipital headache worse on awaking in the morning; sensation of numbness, weakness and awkwardness in the left foot and leg; occasional twitching and pain in the muscles below the left knee and in the left knee; vomiting on several occasions during the early occurrence of these acute symptoms. The awkwardness of the left lower extremity was manifest particularly on standing, and he noticed when his attention was not kept on the left foot that the inside of the foot would gradually raise from the ground and the foot would wobble or balance on the outward edge. This gave him much insecurity and he had to exercise care not to fall although the strength in the leg was meantime quite enough to maintain him in security both in standing and in walking. He noticed also that he stumbled over a slight elevation or any obstacle in his way such as a rug on the floor and that the foot and leg did not "feel" right.

The clonic phenomenon which he speaks of is described by him as follows: "I had a pain in my left knee, a sharp pain, which lasted several minutes, then my leg began to twitch up and down and to have a feeling as if I must reach down and hold it. This lasted several minutes then it went away and I fell asleep." There seems to have been not only a consciousness of clonic spasm in the left leg but the manifestations of it were observable to others. The headache was his most distressing symptom and it continues to be. It was referred to the forehead and to the back of the head—an intense increasing benumbing pain—always worse in the morning and very bad when he makes an effort. The only relief he has had from it, he maintains, was the 24 hours following lumbar puncture.

His wife related he had not vomited for a week preceding his entrance to the hospital, and it may here be stated that he has not vomited in the ten days he has been in the hospital. He does not complain of any other symptoms, although, as will be seen later, he used the left hand undexterously he makes no complaint of it. Mentally he seems quite normal. He is quite reticent and desires to be left alone, but this is interpreted as an index of his suffering.

Physical examination reveals briefly what seems to be a left-sided hemiplegia, the lower extremity being involved much more profoundly than the upper. In walking the left leg is moved in an irregular ataxic way and it is to be observed that it tends to dart and sway to the left. He does not swing the left leg in a semicircle as does the capsular hemiplegic. There is no toe drop but he stumbles over small objects on the floor, and almost invariably trips on the rug as he passes over it. When walking he holds the left upper extremity semiflexed but when his attention is called to it he extends it but is scarcely noticed to swing it. It may quite well be that this position of the left upper extremity is involuntary to conserve his security by balancing. His gait is practically the same when he attempts to walk with eyes closed as when they are open. When he stands with the feet apart or the foot in apposition the tendency is for the left foot to turn over at the ankle and to wobble on the outer border.

Despite this obvious hemiplegia there is no real paralysis of the left lower extremity. He is able to execute every movement. The tap, tap, tap of the

toes of the left foot cannot be done so readily as the right but they can be done slowly but rather awkwardly. The strength of the left upper extremity compares favorably with the right, but it is much less dexterous. There is no hypertonia or deformity. When the patient is sitting or lying the feet assume a natural position save that the big toe is in a state of partial extension and when he stands they grip the ground in fork-prong fashion.

There is a distinct fine tremor of both upper extremities; in performing purposeful acts like the finger-nose and finger-finger tests they become exaggerated and intention-like. It is present on both sides but somewhat greater on the left than on the right and it is to be construed as an ataxia.

The tendon jerks of the left side of the body are all exaggerated. On the right side normal. The disparity between the knee and ankle jerks is no greater than that between the triceps jerks. The direct myotatic irritability is increased over the entire body but it is not more increased on the left than on the right, as a matter of fact it seems even to be livelier on the right.

The plantar reflex of the left side is extensor, of the right flexor. A feeble exhaustible clonus is to be obtained on the left side, none on the right. (The clonus on the left side has become permanent during the past 24 hours.) There is a distinct Babinski phenomenon on the left but not on the right.

The Oppenheim phenomenon is also present. The left abdominal has never been elicited since his entrance to the hospital, left epigastric is sluggish; the right abdominal and right epigastric are both lively; the cremasterics are alike on both sides.

Disorder of sensation. There is no disturbance of tactile or thermal sensibility in any part of the body. On one or two occasions he did not seem to appreciate contact stimuli as keenly in the left leg as in the right. We have never been able to corroborate this to our satisfaction. There is no disturbance of stereognostic sensibility and there is no adiadokokinesia. He does not detect alterations of position in his left toes and foot as distinctly as on the right. There is no disturbance of the postural sensibility of the upper extremity.

Examination of the eyes show them to be entirely normal and there is no elevation of the papillae. There is no limitation in the fields, no disorder of the retinal vessels; but he has a refractive trouble which is readily corrected with glasses.

He has had no elevation of temperature, no particular disorder of his pulse rate and the laboratory examinations are all negative. Dr. Culbert reports the presence of pus in his nose and that his sinuses do not transilluminate very clearly. The x-rays made by Dr. Evans show them to be practically normal.

During the past 24 hours there has been a marked increase in his objective symptoms. He now has astereognosis and asymbolia in the left hand. Marked disturbance of postural sensibility in the left upper extremity and in the left lower and the hemiplegia has become much more pronounced.

REMARKS.

When we take into consideration the onset of the symptoms, the way in which they have developed and their association in conjunction with the character and display of the physical signs, we are led to the conclusion that the lesion which is respon-

sible for his condition must be in the right hemisphere posterior to the fissure of Rolando. The nature of the lesion would seem to lie between a neoplasm and one of vascular origin. In the absence of any alteration in the cardiovascular system and in the absence of its chief cause, lues, a vascular lesion can, I think, safely be excluded. Were it not for the fact that the most constant accompaniment of cerebral neoplasm, namely optic neuritis, is absent, one would have no hesitation in making the diagnosis with much certainty. The rather abrupt onset of the symptoms, the character and location of the headache, the pain and clonic manifestation in the left knee and the unilaterality of the spastic manifestations associated with increasing loss of postural sense in the left lower extremity must be considered fairly pathognomonic. The absence of choked discs in cerebral neoplasm even when situated in the substance of the hemispheres and of very considerable size is not such a rare occurrence as to require comment. When a neoplasm occurs without causing a rapid increase of intracranial pressure optic neuritis may not develop. We do not fully understand what the factors are that lead up to increased intracranial pressure from cerebral neoplasm; but in this instance the fact must be assumed that they do not exist. Concerning the nature of the growth our belief must be wholly speculative. That it is not of a gummatous formation is practically excluded by the state of the serum and cerebrospinal fluid. It might well be a tuberculous growth and have its chief seat in the pia. There is much in the appearance of the patient and clinical course of the disorder that suggests this. Judging from experience with similar cases, however, it is likely that the alleged growth is of a sarcomatous nature.

In regard to the symptoms which he has had for the past year, namely, manifestations of distress and pain in the extremities and joints, it must be said, after careful review of the histories of individuals from whom brain tumors have been removed, that not infrequently they have complained, often over long periods, of symptoms that are interpreted as neurasthenia, which concept is so elastic, that it readily includes the symptoms of chronic rheumatism.

It is proposed to have an exploratory operation done upon this patient as soon as possible, and he will be shown at some subsequent conference.

OPERATION.

On the day following this patient's presentation before the conference, craniotomy was performed by Dr. Elsberg. His condition had become rapidly worse, so that he was semistuporous several hours before he reached the operating room. He was given morphia, gr. 1/6, and there was some doubt whether his stupor then was due to the drug or his cerebral condition.

Description of the Operation. An osteoplastic flap of the right parieto-temporal region was made. The dura was seen to be bulging. To relieve the apparent intracranial pressure a right subtemporal decompression was done. Then an aspirating needle was thrust into the right upper post-Rolandic area. Several drops of a mucoid material were aspirated. Thereupon an opening about two inches in length was made at the point of aspiration and about 50 c.c. of a yellowish mucoid material drained off. Under the microscope this was seen to be made up of red

cells, large phagocytic cells containing detritus, gliomatous tissue and single glioma cells. The opening was closed and the osteoplastic flap replaced. The post-operative temperature was 104, the pulse weak, and the respiration labored and stertorous. A right facial paresis developed. Stimulation did not seem to produce the desired results and patient died at 2.30 P.M. on the day following the operation.

A CASE OF MYASTHENIA GRAVIS OF INTESTINAL TYPE.

DR. WALTER TIMME of the Third Division presented a case belonging in the category of myasthenia gravis of ophthalmoplegic type, but at the same time presenting some symptoms of muscular dystrophy of the thigh muscles. The patient, a manufacturer, 52 years of age, married, with a family of eight children, had been in good health until September, 1914. At that time, due presumably to business difficulties, uncertainties and a pessimistic attitude towards the future, he began to notice that his eyelids began to grow heavy; first one, then after a week or so, the other; there arose an annoying diplopia, and a feeling of general weakness took possession of him. He began to feel excessively fatigued upon slight exertion, his ptosis became worse, his weakness increased, and his condition began to alarm him. He then consulted successively two well-known and competent neurologists. The diagnosis in one case was that of slight ocular palsy due to a mild cerebral hemorrhage. He was advised to take a vacation for a few weeks. He went to Battle Creek from which place he returned unimproved. The second diagnosis then was made of an ocular palsy due to either syphilis or cerebral neoplasm. Syphilis being strenuously denied and the serum Wassermann proving negative, the alternative diagnosis of brain tumor was insisted upon and operation, due to its inaccessible position, declared to be contra-indicated. This hopeless condition could have but one result. The patient sought relief elsewhere—among the Eddyites—and they succeeded partially in restoring his adjustment to the condition. It was only at the earnest suggestion of the family that he finally sought other advice two weeks ago. The examination then revealed the following status: There was a double ptosis, more marked on the left side, which the patient tried to modify with ill success by overaction of the frontalis. There was a divergent strabismus, which closer examination proved to be due to complete fixation of the right globe with only incomplete fixation of the left eyeball—the left external rectus being intact. This condition produced the diplopia. Both fundi were normal and the discs clear with distinct margins and the visual fields were intact. The overactivity of the frontalis produced many transverse wrinkles on the forehead. There was a slight right facial weakness, and also a right palatal weakness. The reflexes were everywhere present and equal excepting that the abdominals and epigastrics could be only occasionally elicited. There was no Babinski sign and no clonus, or tremor, or ataxia. There were no atrophies. Station and gait were normal. The patient declared that on chewing food, his lower jaw easily became fatigued. Walking likewise fatigued him, especially in the extensor thigh muscles and in the hips. This was made more evident when the patient tried to lift himself from a squatting posture several successive times. He finally would place his hands upon his thighs to

get sufficient leverage in a manner suggestive of the pseudo-hypertrophied paralytics. These muscles were then tested for the Jolly myasthenic reaction which proved negative. However, a rapidly interrupted faradic current (118 per minute) passed into the orbicularis palpebrarum of the left side exhausted the muscle within three minutes. The knee jerks were just as active after 100 reactions as at first. The laboratory tests of urine, blood and faeces were practically negative; the blood pressure was 120-130 mm. There were some suggestive signs of a dyspituitarism inasmuch as he had an enormous growth of hair, especially upon his back, where its growth invaded areas distinctly radicular, in position. So that we had a patient in whom the disease of myasthenia gravis had thus far affected the ocular groups of muscles solely, but was beginning to weaken the facial and palatal groups. The dystrophic character of the extensor thigh muscles was of great interest as it placed the case in a transition group between myasthenia gravis and the muscular dystrophies, a fact pointed out and dwelt upon by Dr. Pearce Bailey, who saw the case in consultation at the Neurological Institute. The suggestiveness of a dyspituitary condition is doubly interesting from the fact that several cases of myasthenia gravis are said to have been cured by administration of endocrine gland extracts, notably the pituitary. After this patient had had absolute rest in bed for five days, his ptosis and his diplopia both diminished slightly and there was a suspicion of movement in the external rectus of the right eye. The patient has also been placed on pituitary extract, posterior lobe, gr. $\frac{1}{4}$ t. i. d., and, if possible, will be again presented, before the conference.

A CASE OF HYPOPHYSEAL NEOPLASM WITH IMPROVEMENT AFTER INJECTIONS OF PITUITRIN.

DR. WALTER TIMME of the Third Division showed a case of hypophyseal neoplasm—probably of cystic character, in a woman 44 years of age. She was married, had several children and her history was uneventful up to July, 1913, when she ceased to menstruate.

In September, 1914, she began to have severe headaches and became gradually blind in the left eye. This blindness, however, improved while the right eye vision slowly deteriorated and the headaches remained as before. In this condition she entered the Neurological Institute some two weeks ago. Her neurological condition as to station, gait and reflexes was normal. Both blood and cerebrospinal fluid were negative serologically. She wanted relief from her headaches which were so intense that even her diminished sight was secondary in importance to them. An examination of the visual fields by Dr. Ward A. Holden showed on the left a temporal blindness for red alone, while on the right a complete temporal hemianopia for all color and form was discovered. These findings made absolute what had been previously surmised from an examination of the patient's skull formation and history. She had a somewhat prognathous upper jaw, a broad square chin, a widening of the distance between the molars and an expressionless flattened facies. She furthermore gave a history of polyuria and polydipsia without the presence of glucose in the urine.

REMARKS.

The case is interesting from the antecedent early menopause as a possible causative or better, deter-

mental factor in the pituitary evolution; and also from the fact of the improvement in the left visual field synchronous with the involvement of the right. Such changes may occur in the development of a cyst involving the hypophysis. As the posterior lobe of the pituitary is credited with power to produce rapid secretion and absorption of the cerebrospinal fluid, this patient was treated with injections of pituitrin three times daily. After four or five days the headaches began to diminish so that they were quite bearable. It seems that the right visual field is also a little less contracted than before. In a case mentioned by Elsberg, a complete bitemporal hemianopsia due to hypophyseal condition, disappeared within some weeks as a result of pituitrin injections and there is some reason to hope that a similar fortunate termination may greet us in the case presented.

A CASE OF HEREDITARY BRAIN TUMOR.

DR. FOSTER KENNEDY presented from the Second Division the case of G. E. L., a male, age 16 years, who was admitted to the hospital on Dec. 29, 1914, complaining of occipital headache, staggering gait, double vision and occasional dyspnoea. *His father died of fourth ventricle tumor eight years ago.* There is a family history of epilepsy. Patient had always been well, has been a good athlete and above the average in his school lessons. The onset of the present condition was in April, 1914, when he began to have severe headaches coming on twice a week in the mornings with frequent vomiting of projectile character. In the autumn these symptoms increased in frequency and severity and patient began to feel dull, apathetic. In the beginning of December, 1914, patient had attacks of diplopia and on the 15th of December, at night, his respirations fell to 12 per minute and his pulse rate to 58.

Examination on the 28th of December showed that he had a very slight blurring of both optic discs; a very slight weakness of the left external rectus; coarse nystagmus on looking to the right and fine rapid nystagmus on looking to the left. Marked *vorbeizeigen* on the left side. No marked ataxia in the arms, some staggering to the left, an ill-marked *adiadokokinesis* on the left. The plantar reflexes were not obtained on either side, knee jerks and ankle jerks were brisk and equal as were also the abdominal reflexes.

On the second of January, 1915, there seemed to be considerable advance in papilloedema; pointing but not marked, but there is a coarse rhythmical non-constant tremor in both hands more marked on the right than on the left.

On the fourth of January left external rectus weakness very much more advanced. Plantars right absent, left flexor.

January 10th, weakness definitely present in right sixth and almost complete palsy in left sixth. Cranial nerves otherwise normal. Abdominal reflexes equal.

January 15th, bilateral complete external rectus palsy. Deep reflexes on the left side greater than those on the right; abdominal reflexes equal. Severe left-sided occipital tenderness and headache.

January 29th, tenderness left frontal and left mastoid and occipital region, the right plantar is indefinite, often extensor, the left definitely flexor. Patient says objects seem dim in the central part of the left visual field. This is not so on the right side.

This patient was shown as a case of brain tumor of obscure localization. First diagnosis made upon him was that of lesion of the left cerebellum. Against that diagnosis is the inconstancy of motor ataxia on the left side. An intra-pontine lesion is possible but the double sixth paralysis is of the type associated with peripheral rather than nuclear lesions. It is proposed to do a puncture of the corpus callosum in order to relieve pressure and afford opportunity for further observation with a view to radical procedure. Of special interest in this case is the hereditary tendency to brain tumor.

Book Reviews.

Fewer and Better Babies, or The Limitation of Offspring by the Prevention of Conception; the Enormous Benefits of the Practice to the Individual, Society and the Race Pointed Out and All Objections Answered. BY WILLIAM J. ROBINSON, M.D., Chief of the Department of Genito-Urinary Diseases and Dermatology, Bronx Hospital, Editor of *The Critic and Guide*, Author of "Sexual Problems of To-day," etc., etc. With an introduction by A. Jacobi, M.D., LL.D. New York: The Critic and Guide Company. 1915.

The author's thesis, as shown in the title, is that "under any conditions, and particularly under our present economic conditions, human beings should be able to control the number of their offspring;" that to accomplish this purpose "the knowledge of preventing undesirable conception should not be considered criminal knowledge, that its dissemination should not be considered a criminal offence punishable by hard labor in federal prisons, but that it should be considered knowledge useful and necessary to the welfare of the race and of the individual, and that its dissemination should be as permissible and as respectable as is the dissemination of any hygienic, sanitary or eugenic knowledge." The author proceeds to defend his thesis in a series of chapters dealing with the orthodox remedies, the question of race suicide, the moral and religious issues involved, and various matters of divorce, abortion, prostitution, work and wages. Chapter xxviii, devoted to the best, safest and most harmless means for the prevention of conception, mechanical and chemical, and chapter xxix on the means for the prevention of conception which are disagreeable, uncertain or injurious, have been deleted by the censor, acting under the United States Criminal Code, Section 211 and Section 1142 of the Penal Law, New York Statutes; so that the author has not been permitted, under the law, to enlighten his readers as to his views concerning

the ways and means by which unrestricted sexual intercourse may not result in conception.

The author states his position and maintains it with force and clearness. No one will disagree with him in his view that man and wife should not bring into this world more children than they can rear, and with the assistance of the State educate to useful citizenship. But a reviewer's space does not permit a discussion of the author's opinions in regard to the moral and ethical questions involved, nor of the reasonably probable results of promiscuous sexual relations under legalized methods intended to frustrate the laws of nature. Perhaps it has not occurred to the author that among the various purposes of Divine Providence in placing man on this footstool is that of affording him opportunity, while giving him freedom of will, to train himself in self control and in ruling his own spirit.

Précis de Chirurgie de Guerre. Par EDMOND DELORME, Médecin Inspecteur Général de l'Armée; Ancien Président du Comité Consultatif de Santé de l'Armée; Membre de l'Académie de Médecine; Membre et Ancien Président de la Société de Chirurgie. Paris: Masson et Cie. 1914.

A small book of 200 pages, printed in Paris, immediately after the outbreak of the present unexpected war. It gives the most recent French views upon gunshot wounds, with brief chapters upon weapons, missiles and side arms. The outlines of small arm bullets must be correct, but are for the most part, quite unlike what we have been led to believe of most of the foreign armies.

The book is unexpectedly complete and detailed, for so small a bulk; it is of peculiar interest at present; a good English translation is most desirable, for the precise shades of meaning of the French language are still, unfortunately, beyond the great majority of American surgeons.

The Feces of Children and Adults. Their Examination and Diagnostic Significance, with Indications for Treatment. By P. J. CAMMIDGE, M.D. (Lond.), Containing 13 full-page plates, 7 of which are colored, and 96 illustrations in the text. New York: William Wood and Company. 1914.

This book, which is based on Hecht's "Die Faeces des Säuglings und des Kindes," and Schmidt and Strasburger's "Faeces des Menschen," also contains a considerable amount of original material, the result of the author's own observations. It contains a vast amount of information on the subject, which is well arranged and easily located by means of an unusually

good index. It will be of use to everyone who wishes to examine the feces, whether superficially or in detail. The chapters on the clinical inferences to be drawn from the results of the analyses are instructive. It would have been better if the author had left out the section on the artificial feeding of infants, a subject with which he is evidently not familiar.

Cancer. Its Cause and Treatment. By L. DUNCAN BULKLEY, A.M., M.D. New York: Paul B. Hoeber. 1915.

This volume, based on a series of six lectures by the author at the New York Skin and Cancer Hospital, presents his view as to the metabolic origin of cancer and its rational dietetic and medical treatment. His results are summarized in a series of thirty-one conclusions. Whatever may be one's agreement or disagreement with these, the author's theory deserves judicial consideration like many others that are advanced towards the solution of this enigma of pathology, since it represents a logical and rational contribution to the literature of the subject. The volume closes with a selected alphabetic bibliography of ninety titles.

Philadelphia General Hospital Reports. Vol. 9. Edited by AUGUSTUS A. ESHNER, M.D. Philadelphia: Dunlap Company. 1914.

This belated report of the Philadelphia General Hospital records the scientific and literary work of the staff of that institution during the year 1913. It consists of a series of twenty-seven papers by members of the staff, three obituary memorial notices, and the very brief report of the chief resident physician. Many of the papers are reprinted from several medical periodicals. The resident physician's report records the improvements and repairs made during the previous three years and notes others that are needed. The volume is of interest as a record of hospital productive activity.

Quain's Elements of Anatomy. Eleventh Edition. Editors: SIR EDWARD ALBERT SCHAFER, LL.D. Sc.D., M.D., F.R.S., Professor of Physiology and Histology in the University of Edinburgh; JOHNSON SYMINGTON, M.D., F.R.S., Professor of Anatomy in the Queen's University of Belfast; and THOMAS HASTIE BRYCE, M.A., M.D., Professor of Anatomy in the University of Glasgow. In four volumes, Vol. IV, Part 1. Osteology and Arthrology, by T. H. BRYCE. London: Longmans, Green and Company. 1915.

This first part of the fourth volume of Quain's Anatomy continues the production of this latest eleventh edition of a standard Scot

tish text-book. It forms in itself a complete monograph on the bones and joints. The Basle nomenclature has been in great part adopted; the text has been thoroughly revised and much of it rewritten; new sections on the development of the skeleton have been added; and the paragraphs dealing with variations have been expanded. The work is illustrated with 247 text figures and 28 new colored plates. An appendix contains an elaborate bibliographical index of recent literature on osteology and arthrology. This volume maintains the high standard of merit of its classic original and of the preceding volumes of this edition.

Student's Manual of Gynecology. By JOHN OSBORN POLAK, M.Sc., M.D., F.A.C.S., Professor of Obstetrics and Gynecology, Long Island College Hospital; Professor of Obstetrics in the Dartmouth Medical School; Gynecologist to the Jewish Hospital; Consulting Gynecologist to the Bushwick, Coney Island, Deaconess' and Williamsburgh Hospitals, Brooklyn, and the People's Hospital, New York; Fellow American Gynecological Society, New York Academy of Medicine, etc. Illustrated with 100 engravings and 9 colored plates. Philadelphia and New York: Lea and Febiger.

This new book represents an effort to present a concise picture "of the pathology and symptomatology of those diseases peculiar to women, as well as a brief summary of the accepted principles of treatment." The purpose is praiseworthy and in places in the book the work is well done, but it ought to have been done better by Dr. Polak, and will have to be done better to meet the need which exists. It is to be hoped its defects will be remedied in a new edition, which should include revision.

There are numerous lapses from the precision which is essential to accurate conciseness. The first page of the text may be cited by way of making clear what is meant: "The important functions of the genital organs in woman are the processes associated with reproduction, *i.e.*,

"1. The alterations in the uterus and ovaries by which menstruation is established, and by which its periodic recurrence is maintained and finally discontinued.

"2. The relation of the sexes in copulation.

"3. The fecundation and nutrition of the ovum.

"4. The processes by which the matured product attains a separate existence. These functions occur at definite physiologic periods in the life of the human female, *i.e.*

"The period of infancy and adolescence, or childhood.

"The period of sexual activity (maturity).

"The period of senility."

To the mind of the student, then, we have presented four functions of the genital organs, performed during three periods in the life of the individual. One has but to consider this analysis from the point of clearness to see its inadequacy. There is a condensed statement, but it would cloud rather than illuminate the mind of the student. Seemingly clear, on investigation it lacks insight.

On page 43, the left ureter is pictured as lying in front of the bowel. On page 51 it is stated that passing the "sound or probe into the uterus" "is a dangerous procedure." This categorical statement deserves an amplification it does not receive. On page 203 is the statement that "complete prolapse" "is where the uterus is nearly without the vagina." (The italics are the reviewer's). On page 274: The cause "of exfoliative endometritis" (membranous dysmenorrhea) "is chronic endometritis." The pathologist will hardly agree to this.

These few illustrative quotations are not characteristic of the whole book. But the student will not be able to discriminate among statements which he meets for the first time.

Human Anatomy. A Complete Systematic Treatise by English and American Authors. Edited by C. M. JACKSON, M.S., M.D., Professor and Director of the Department of Anatomy, University of Minnesota. Fifth edition, revised and largely rewritten. Philadelphia: P. Blakiston's Son and Company. 1915.

This fifth edition of a standard Anglo-American text-book of anatomy maintains the merits of preceding editions. It was the first general text-book of anatomy in English to adopt the Basle nomenclature, and this has been consistently retained in its Anglicized form. In the present edition the attempt is made for the first time to discriminate systematically in the use of sizes of type, the more fundamental facts being printed in large type, the details in smaller. All the sections have been thoroughly revised and there has been a re-arrangement of some of the subject matter. The teeth have been transferred from the section on osteology to that on the digestive system. The tongue and nose are transferred respectively to the digestive and respiratory system, except the portions forming the organs of taste and smell, which have been retained in the section on the special senses. The ductless glands have been included in the section on the skin. The book is illustrated with 1182 figures, 358 of which are printed in colors. The authors of the various sections are for the most part the same as in the fourth edition, but the retirement of Sir Henry Morris and of Professor McMurrieh, as editors, has placed this important duty in the hands of Dr. Jackson, who is to be congratulated on the success with which it has been performed.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JUNE 24, 1915.

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication and all other communications for the Editorial Department should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

SOME OF THE WORK UNDER THE THOMAS THOMPSON TRUST.

THERE has lately been published the report of an investigation into the extent and care of sickness in Dutchess County, N. Y., made by the committee on hospitals of the New York State Charities Aid Association, at the request of the Thomas Thompson Trust of Boston, which is primarily interested in the improvement of social conditions and engaged in active work in the town of Rhinebeck, in this county, and in Brattleboro, Vermont. In the former town the care of the sick centers in Thompson House, established in 1903 in Rhinebeck village by the trustees of the trust. Originally used as a nursing headquarters and as a home for indigent sewing women, this has gradually developed into a small hospital, and it now has a

capacity of fourteen beds (one for every 250 of the population).

It was more important to have more exact knowledge of the sickness which had occurred in the county, in order to draw trustworthy conclusions as to how adequately or inadequately the existing public and private facilities were meeting the needs of the community. With the exception of certain infectious diseases, reported incompletely, at best, to the health officers, there are no public records of sickness in Dutchess County—a condition true, however, of the county in general. The method usually employed for estimating the amount of sickness is to assume a certain morbidity rate for each disease, based upon the recorded death-rate for that disease. This is arbitrary, and naturally fails to throw any light on the kind of care the patients received or on the conditions attending or contributing to their sickness. In this investigation the plan was to secure, directly from the families in which it had occurred, as full and accurate data as possible concerning sickness, including the medical and nursing service obtained, its efficiency and cost, the need of and the demand for domestic assistance in the homes where sickness occurred, and the efficiency with which the demand was met. The attending physician was also consulted, either personally or by letter, about each recorded case of sickness; in this way the statements made were substantiated, and the medical viewpoint as to the character of the sickness and the adequacy of the care of the patient ascertained. By finding out the character of the sickness which actually occurred in certain typical communities during a specified length of time, and by determining the conditions under which it existed, its treatment, and the apparent results of the treatment, it was thought that data might be secured which, when analyzed, would point to improvements in the methods of caring for the sick and of preventing disease. It was not always possible, however, to learn the real cause of the sickness recorded. The family seldom had any idea of the cause, and was often vague as to the exact duration of the illness, and the physicians, especially those in the rural sections, were equally vague on these points. It is not very creditable to the profession to learn that their records were generally found to consist solely of the number and cost of the calls made, and, if the bill had been met, even these scant data had usually been de-

stroyed; while there were practically no records kept of patients who had paid the physician's fee at the time of the call. This inquiry is, so far as known, the first systematic attempt which has been made to secure direct and detailed information concerning sickness in the home. When the plan of the investigation was presented to the Poughkeepsie Academy of Medicine the interest of that body was at once aroused, and it is stated that throughout the investigation the coöperation afforded by it was of the greatest value.

The study was an attempt to secure reliable data relative to sickness which had occurred during a sixteen-month period in certain selected communities; these comprising the typical rural townships of Rhinebeck, Stamford, Milan and Clinton, which are contiguous to each other, and the fourth ward of Poughkeepsie, which was chosen as being more typical of that city as a whole than any other one ward. In this ward of Poughkeepsie and in the town of Rhinebeck, which includes the two village corporations of Rhinebeck and Rhinecliff, a house-to-house canvass was made to inquire of every family concerning cases of illness during the period covered; but as the time allowed for field work was limited, it was impossible to conduct such a detailed canvass in the other towns mentioned. The importance of the findings of this house-to-house canvass of selected districts of Dutchess County is regarded as lying in the fact that there is every reason to believe that the amount of inadequately cared for sickness discovered is typical of what one may expect to find in very many other communities, not only in the state of New York but throughout the nation. Here is a group made up of a small city and several country communities in normal times (1912-13)—no unusual epidemics, no extraordinary social or industrial conditions—during a period shown by reported deaths, reported cases of contagious disease, and the unanimous testimony of physicians to have been a "light year" for sickness. If Dutchess County varies from the normal, it varies in having had a better chance to improve itself than many other communities, for it has favorable conditions which other communities lack, as, for example, Vassar College, large charitable and benevolent endowments, wealthy and public-spirited citizens, nearness to a great city like New York, and ample steamboat facilities on the Hudson, as well as trunk line railroad service. If, under these circumstances, conditions are not what they should be, it is reasonable to

suppose that in less favored communities they are at least equally bad. Reference to the section of the report treating of individual cases of illness shows the existence of many striking instances of neglect and of unnecessary suffering. Under present circumstances the general medical and surgical hospital facilities appear to be inadequate; just how far they could be made to meet the need were disease-producing conditions not so widely tolerated, and were there an appreciable amount of organized home care of the sick and of preventive work, is a question. In the rural districts especially, little effort has been made to check infection. There are, moreover, no facilities for the treatment of alcoholic and early psychopathic cases, nor are there adequate provisions for the care of the feeble-minded and epileptic. Whether the present facilities for maternity cases are sufficient is also a matter to be considered. The medical inspection of school children is also inefficient, and the after-care which such inspection should necessarily involve is practically never given, at least in the rural districts. Rhinebeck town, however, is exceptional in this respect, and although the school nursing was intermittent until the winter of 1913-14, the importance of the work is recognized and continuous effort is being made to meet the problem presented. Efficient attendance, such as that necessitated in any plan for providing adequate care for the sick is not always available. Trained nurses are obtained, it is true, from various centers, but no attempt is made in the county, by organization, to make sure that those who most need the services of such nurses secure them, or to see that there is a sufficient supply of untrained nursing and household service, though this kind of service makes up over 60% of that needed in homes where there is sickness.

Closely involved in the service to the sick, it is held, are the still more important questions of preventing sickness by the education of the community in health matters and by doing away with disease-breeding conditions. Any thorough-going attempt to deal properly with illness in a community must find the proper balance between institutional and home work; it must also find the balance between the palliative work, whether in home or hospital, which relieves suffering due to sickness and the preventive work which teaches people how to escape disease and also removes the insanitary conditions which give rise to disease.

THE PROPHYLAXIS OF FEEBLE-MINDEDNESS.

IN another column of this issue of the JOURNAL we publish an important brief communication by Dr. Frankwood E. Williams, executive secretary of the Massachusetts Society for Mental Hygiene, on "Psychopathic Hospitals and Prophylaxis." At a monthly meeting of the Monday Evening Club held in Boston recently, Dr. Williams gave an address on the subject of the cost to the community of caring for its feeble-minded. In this address Dr. Williams pointed out the great possibility of mental prophylaxis as it can be practiced in the psychopathic institutions in the prevention of the increase of the number of feeble-minded in the community, a class whose cost to the state exceeds that of almost any other group of dependents, with the exception of the tuberculous.

"When a state has to expend each year over \$4,000,000 for the support of any one group of its population, that group presents a serious problem. When Massachusetts first began to provide public care for its insane, the matter appeared to be a comparatively simple one. One hospital providing for 500 patients was considered sufficient. In less than a hundred years the state finds itself with sixteen institutions, caring for some 21,000 patients a year at a cost, last year, of \$4,547,768. Patients are being admitted to the state hospitals at a rate of over 3000 a year. Some of these recover, but the majority are incapacitated the rest of their lives. The efforts of the state up to the present have not only not lessened the problem, they have not even kept pace with it. And the reason is not far to seek. Providing for the care of the mentally diseased after the damage has been done, important and essential as a humanitarian measure, will have little effect in the prevention of mental disease. The emphasis of our efforts is misplaced. Greater stress must be placed upon efforts at prevention. A hundred years ago this could not be done, as the causes of mental disease were unknown, but today we do know that heredity, alcohol and syphilis are the three most important factors producing mental disease.

"There is one family in this state, and it is not an exceptional family of its kind, composed of a feeble-minded father and mother and nine feeble-minded children. The parents have been unable to care for their children, and the state has found it necessary to take charge of them. To care for these children the commonwealth has expended over \$16,000 up to Jan. 1 of this year."

This address acquires additional significance in conjunction with Dr. Williams' article in this

issue of the JOURNAL. Dr. Williams points out a distinct group of individuals whose psychopathic defects proceeding from definite causes, may be temporary and may be prevented from development by judicious observation and treatment. Such a duty is the function of psychopathic hospitals and clinics and its importance to the nation is almost incalculable when it is considered that successful mental prophylaxis not only prevents the immediate suffering of the individual and his family but also the perpetuation of similar defects in future generations with the immense cost involved in the subsequent care of those who thereby become dependent.

VENEREAL PROPHYLAXIS.

Now that such excellent results are reported by the army and navy medical officers from the use of the prophylactic packet in reduction of venereal incidence among the enlisted men, it seems timely to urge the employment of similar methods elsewhere where venereal diseases are likely to be prevalent. Such a place exists particularly in the merchant marine. No organized effort has been made to teach the members of this class prophylaxis, although as a body in peace times they compose a class very much larger than the combined strengths of military organizations. This government is put to a large expense in the maintenance of many marine hospitals and hospitals for the insane. In the former the greater part of the patients suffer from acute or chronic venereal diseases or their complications. In the latter many of the mental or nervous disorders are directly traceable to venereal infection. Crews of vessels who are entitled to treatment in these institutions should be required to establish among themselves the approved methods of prophylaxis. Aside from the very few accidents occurring aboard, the greater part of the incapacity during any one voyage is due to venereal disease. The cost of supplying a whole crew with the prophylactic packet would hardly equal the cost of treating one case of disease, and would be less than the loss occurring by the incapacity of such a member during treatment.

Because of the wide range of travel of merchantmen they would act as missionaries in this work of prophylaxis among other crews with whom they came in contact. The venereal in-

fection of any given community is largely augmented by importations from vessels touching such places, and it will be a step in the eradication of venereal infection when these sources are put under control.

The plea that the teaching of prophylactic measures is an incentive to immorality is too theoretical and problematic to deserve more than passing attention, in the face of the suffering and injury as well as mortality induced by these very preventable diseases. If only those infected through immorality were concerned in this question one might almost be tempted to let them take their "medicine"—though such a point of view is unworthy of progressive thinking—but in fact it is the innocent who suffer most, either by infection directly, or indirectly, or through heredity. Venereal disease when once established has a tendency toward permanence, whereas immorality is a variable factor, changing with the composition of the particular social community and with its code of morals. No case of ophthalmia neonatorum or congenital syphilis has ever been reported as the result purely of a breach of the moral code.

A NEW FIELD FOR AMERICAN MEDICAL WRITERS.

It is given to some men to express their opinions in fluent English and among our profession those fortunate ones are found most often in the pages of the medical periodicals. The works of American medical writers, with a few notable exceptions, have not been found much in the columns of our English contemporaries, and there are several reasons for this.

One is, that the natural tendency of the writer is to publish his work in his own country where his audience will probably be more sympathetic. Another is, that the editors of journals in foreign countries, such as England, prefer to use the works of their compatriots. Then might be added the extra time and expense involved in correspondence across the ocean.

The present European conflict, however, gives rise to a different situation. In England a great many of the doctors are at the front, those who are left are harder worked than usual and so there is little time for literary labors. On this account some of the English journals have suspended publication temporarily while others are obviously suffering for want of material.

It is in the power of American medical men

to relieve this situation somewhat, if they will. Let them send some of their papers to English journals for a time at least and it is probable that they will be warmly welcomed. It may be also the means of bringing about professional intimacies between the physicians on the other side of the Atlantic and this, to their mutual advantage.

MORE COSMETIC SURGERY.

APART from his function in the relief of physical suffering, the surgeon is often called to ease another kind, a more refined but none the less acute form, the psychic suffering attendant upon deformity or disfigurement. The domain of plastic surgery is large and increasing; and although furnishing entertainment to the comic writers and sneeringly referred to by some colleagues as "beauty doctors" the practitioners of this art perform a very real service to the community.

In the *Annals of Surgery* for May, 1915, Dr. Leonard Freeman adds to the resources of the surgeon interested in this specialty by a valuable contribution. He has devised a treatment for so-called "false keloid" which now and then appears sometime afterward to mar an otherwise successful operation. He thinks that this blemish is due to tension on the scar, causing a hypertrophy of the cicatricial tissue. Tubercular patients appear to be particularly predisposed, so that it is found as an aftermath to excision of tubercular cervical glands, in which location it is a great disfigurement, especially in women.

Dr. Freeman treats this condition by the free transplantation of fascia from some other part of the body, which he sutures to the superficial fascia on one side of the wound and to the deeper tissues on the other. He describes two cases where he removed these growths and transplanted the fascia with gratifying results. The method, he says, is of no value in true keloid.

DRUG REGISTRATION.

PHYSICIANS are reminded that their drug registration under the provisions of the Harrison law must be renewed on or before July 1, 1915, for the ensuing year. This may be done upon payment of \$1.00 at the office of the local collector of internal revenue. For the convenience of physicians, the same registration number previously held will, upon request, be re-issued to each physician.

MEDICAL NOTES.

SECOND ANNUAL MEETING OF THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.—The second annual meeting of the American Association of Immunologists was held at the New Willard Hotel in Washington, D.C., on Monday, May 10. Dr. James W. Jobling of the Vanderbilt School of Medicine, Nashville, Tenn., was elected president, Dr. George P. Sanborn of Boston, Mass., vice president, and Dr. John A. Kolmer of Philadelphia, Pa., was elected to the council for the ensuing year.

Dr. Oliver S. Hillman of New York City, and Dr. Victor C. Vaughan, Jr., of Detroit, Mich., were elected active members, and Professor Emil Abderhalden of Halle, Germany, Professor Victor C. Vaughan of Ann Arbor, Mich., and Professor Edward C. Rosenow of Chicago, were elected to honorary membership.

The Immunologists now have 60 active members and 20 applications for membership. The total number of members allowed by the constitution and by-laws is one hundred. Dr. Martin J. Synnot of Montclair, N. J., is secretary.

SYRACUSE UNIVERSITY.—At the commencement exercises of Syracuse University the honorary degree of LL.D. was conferred upon Dr. Henry L. Elsner, professor of medicine in the Medical Department of the University.

LOW WEEK'S DEATH RATE IN NEW YORK.—During the week ending June 12, 1497 deaths were reported as against 1365 for the corresponding week of last year, an actual increase of 114 deaths. If, however, the increase in the population is considered, there were only 60 more deaths. In other words, if the death rate prevailing during the corresponding week of last year had prevailed during the past week, there would have been 1419 deaths instead of 1365.

The death rate for the past week was 13.29 as against 12.75 for the corresponding week of last year.

The increase was due to the higher mortality from measles, diarrheal diseases, lobar pneumonia, influenza, heart diseases and diseases of the nervous system. The increase in the number of deaths from organic heart disease is somewhat offset by the decrease in the number of deaths from chronic Bright's disease. The death toll was heaviest at the extremities of life.

The mortality of infants under one year and of persons over 65 showed a very material increase, despite the temporary increase in the number of deaths which occurred in the city last week.

The death rate for the first 24 weeks of 1915 is .63 of a point lower than the rate for the corresponding period of 1914.

AMERICAN ASSOCIATION OF ANESTHETISTS.—The third annual meeting of the American Association of Anesthetists was held in San Francisco on June 21, under the presidency of Dr. Charles K. Teter of Cleveland. At the two scientific sessions numerous addresses were presented. The presidential address was on "Nitrous Oxide Oxygen Anesthesia in Obstetrics."

EXPERIMENTS IN THE PRODUCTION OF ARTIFICIAL IMMUNITY AGAINST TUBERCULOSIS IN CATTLE.—In 1900 the State Livestock Sanitary Board of Pennsylvania began the work of experimenting upon the immunization of animals against tuberculosis. After the possibilities of this work were realized in 1903, a request was made to the Legislature for a larger fund and the purchase of a farm for the continuation of this and other researches in the field of animal diseases. A report of this work has been published by the Board in a pamphlet called Circular No. 32, written by S. H. Gilliland, M.D., State Veterinarian of Pennsylvania. Dr. Gilliland draws the following conclusions from his experiments:

1. Intravenous injections of tubercle bacilli from human sources, non-virulent for cattle, are capable of conferring an immunity in cattle against tuberculosis sufficient to withstand natural infection by association with tuberculous cows.

2. The length of the immunity conferred has not been determined definitely, but it is believed to diminish gradually after two and one-half years.

3. The vaccinated animal during the period of vaccination and for some weeks afterward is more liable to contract tuberculosis than a normal animal. The natural resistance of the animal is apparently lowered during the time of vaccination.

4. The interval between the vaccinations should be of a sufficient length to allow any reaction following the previous vaccination to subside entirely.

5. The degree of immunity obtained in the animal depends to a certain extent upon the number of vaccinations and the amount of vaccine administered.

6. The vaccine should be prepared so it contains no clumps of bacilli and should be administered fresh.

7. A number of the vaccinated animals may give a typical tuberculin reaction following the vaccinations for a period of 20 months. These animals may or may not show lesions of tuberculosis at autopsy.

8. Vaccine administered to animals, already infected with tuberculosis is capable of retarding or holding in check the progress of the disease.

9. The milk from immunized cows when fed over a long period of time appears to increase the resistance of calves and pigs.

10. Vaccination of calves against tuberculosis is of assistance in the eradication of tuberculosis from a herd if done under the proper conditions.

11. Until further knowledge is obtained in regard to the destruction or outcome of the living tubercle bacilli constituting the vaccine, no practical method for the immunization of milk-producing animals under ordinary conditions can be advocated.

THE MAYO FOUNDATION.—In the issue of the JOURNAL of June 10, we reported on the progress of the arrangements being made by the University of Michigan for the acceptance of the fund offered by the Drs. Mayo of Rochester, Minn., for medical research work under the auspices of the University. The report of the special committee of the board of regents was presented on June 5, and was adopted by a unanimous vote of the ten members present. Officers of the board were authorized to enter into legal agreement with the Foundation governing the relationships. The terms of the agreement provided among other things: That the board of regents of the University is by law required to manage the University and appoint its professors and employees and fix their salaries and may accept in trust gifts and bequests upon the terms and conditions on which they are granted: That the foundation gives and grants to the university free of charge the right to use for medical and surgical education and research space and rooms and equipment in a certain building in Rochester, together with all clinical and other materials and opportunities for graduate medical and surgical work available at the Mayo Clinic, St. Mary's Hospital, the Kahler Sanatorium and the Colonial Sanatorium in Rochester, for a period of six years after September 1, 1915. That until September 1, 1921, the net income of each of the trust funds shall remain in the hands of the trustees as an added increment to the principal of the funds. That from and after September 1, 1921, the principal of the funds and all accumulations to that date shall be turned over to and become the property of the University.

MORTALITY RATES SINCE 1815.—Mortality rates computed for the four leading cities of New York, Boston, Philadelphia and New Orleans of the last century give the following interesting figures:

The mortality from all causes during the first 25 years was 28.1 per 1,000 of population, increasing to 30.2 during the second quarter-century, diminishing to 25.7 during the third, and finally to 19.1 during the fourth. The highest death rate prevailed in 1832, when it attained

48.4 per 1,000 of population, due primarily to the yellow-fever epidemic in New Orleans, which raised the death rate in that city to 140.9 per 1,000 of population. Two other conspicuous years in the sanitary history of the four cities were 1849 and 1854, when the death rate attained 42.0 and 41.1 per 1,000 of population, respectively, due chiefly to cholera and yellow fever. The balance of mortality for the last half-century, by principal causes, rated per 100,000 of population is shown in the table below:

	1864-1888	1889-1913
Smallpox	39.5	2.4
Asiatic cholera	7.5	0.01
Yellow fever	14.0	0.6
Scarlet fever	66.3	18.8
Diphtheria and croup	123.2	58.3
Typhoid and typhus fevers	53.1	24.7
Pulmonary tuberculosis	364.9	223.3
Pneumonia	188.5	232.0
Stomach and intestinal diseases	298.6	196.2
Heart diseases	103.7	164.6
Nephritis	78.7	131.7
Cancer	46.4	72.1

The rates for the city of Boston for these periods are as follows:

The quarter-century death rate of Boston increased from 21.3 per 1,000 of population during the period from 1815—1839 to 25.0 during 1840—1864, but decreased to 23.8 during 1865—1889, and diminished to 19.5 during the quarter-century ending with 1914. High rates prevailed in 1821, 1849 and 1872, on account, respectively of measles, cholera and small-pox. The lowest rate, 16.2 per 1000 of population, prevailed in 1914. The balance of mortality for the city of Boston for the last half-century, by principal causes, rated per 100,000 of population is shown in the table below:

	1864-1888	1889-1913
Pulmonary tuberculosis	381.8	219.8
Stomach and intestinal diseases	225.5	165.5
Pneumonia	179.5	223.1
Diphtheria and croup	121.9	59.4
Heart diseases	109.0	189.8
Scarlet fever	61.4	17.3
Bright's disease	53.7	87.0
Typhoid and typhus fevers	51.8	23.0
Cancer	51.5	89.0
Smallpox	19.7	2.2
Cholera	0.3	0.01
Yellow fever	0.1	0.01

AFFILIATION OF COLUMBIA UNIVERSITY AND PRESBYTERIAN HOSPITAL.—In the JOURNAL of May 13, 1915, was reported the proposed affiliation of Columbia University and the Presbyterian Hospital in the establishment of a larger and more serviceable medical school with increased hospital facilities. The plans for the development of this affiliation require the erection of a

plant on the proposed site at Washington Heights, to consist of a building for administration; a building or buildings of much greater capacity than the present group on 59th street to house the medical sciences, the Crocker Cancer Research laboratories, and a School of Sanitary Science and Public Health; a building or buildings to house the Hospital, with an ultimate capacity for at least 1200 patients; a building for the Vanderbilt Clinic, to serve also as the out-patient department of the Hospital; dormitories for the accommodation of at least 400 medical students, with an adequate dining hall for both students and instructors; and a building to house a training school for nurses and to serve as the nurses' home. The plan also provides space for a possible building for the Sloane Hospital. A considerable portion of the total area is to be left for the present unoccupied for the addition of future institutes or foundations which may become necessary as the result of the development of medical science, or which may affiliate themselves with the Hospital and the University.

EUROPEAN WAR NOTES.—It is announced that Dr. John J. Stack of Dorchester has volunteered to go to Serbia to assist Dr. Strong in his work in the suppression of the typhus fever epidemic in that country. Dr. Stack will be accompanied by the five following students of the Harvard Medical School: Charles B. Spruit, 1915; Daniel C. Hankey, 1915; Henry A. Buckner, 1915; Joseph H. McGuire, 1915, and William Sheffield, 1918. It was expected that this party would sail on June 18.

Report from Nish, Serbia, by way of London on June 14, states that there has been formed in that city a central sanitary committee composed of the chiefs of the American, British, French, Russian and Serbian sanitation staffs. This committee is under the presidency of Sir Ralph Paget, with whom Dr. Richard P. Strong and M. Grouitch, under secretary of foreign affairs, have recently made a tour of inspection of the principal hospitals in northern Serbia.

On June 19 the totals of the principal New England relief funds for the European War reached the following amounts:—

Belgian Fund.....	\$263,120.97
Polish Fund.....	47,172.21
Serbian Fund.....	32,998.92
Lithuanian Fund.....	30,000.00

BOSTON AND NEW ENGLAND.

COMPETITION BY DAIRYMEN FOR CLEAN MILK.—It is reported that the competition for clean milk and the award of prizes by the Board of Agriculture of Massachusetts is arousing among the dairymen keener interest than ever before.

The number of entries is twice as large as in previous years. About 200 cash prizes are offered, the highest prize for an individual being \$50. Districts may compete for prizes of \$100 and \$125. These are awarded at the winter meeting of the Board of Agriculture held in Boston, which promises to be the largest meeting in the interests of clean milk held in this state. For the north-eastern district the entries will be closed on June 30, the central district July 31 and the western district August 31.

TUBERCULOSIS DISPENSARY IN NORTHAMPTON.—It is announced that the Northampton Society for the Prevention and Control of Tuberculosis has arranged with the local board of health to establish a dispensary for the treatment of tuberculosis, where free examination and advice will be given to those who cannot afford to pay. The district nurses will share in the work of the dispensary and the expense will be met by the anti-tuberculosis society and the board of health. The arrangement has been approved by the State Board of Health and complies with the state law requirement for establishment of tuberculosis dispensaries in the cities. The dispensary will be opened within two weeks.

MASSACHUSETTS SCHOOL FOR THE FEEBLE-MINDED.—The annual report of the Massachusetts School for the Feeble-Minded at Waltham, shows that there were 218 admissions during the year, and 77 discharged cases. The hospital is much overcrowded and additional accommodations are urgently needed. Patients are obliged to sleep on improvised beds in corridors and on the floor. The Binet-Simon psychological tests have been applied to all the inmates with the following results:

Mental ages at less than a year	25
1 year,	157
2 years,	132
3 years,	150
4 years,	95
5 years,	118
6 years,	166
7 years,	276
8 years,	250
9 years,	163
10 years,	104
11 years,	29

Total 1,665

PRUDENTIAL HOSPITAL ASSOCIATION.—It is announced that the old building of the Children's Hospital on Huntington avenue, Boston, has been purchased by the Prudential Hospital Association Company of the State of Massachusetts, Inc., which plans to make extensive alterations in the building, thereby converting it into a modern five-story public hospital with 220 beds for general medical and surgical cases.

MEDICAL SUPERVISION OF SCHOOLS.—It is reported that there are being made plans by the school committee of Boston and Mayor Curley to place the work of health supervision of the public school under the jurisdiction of the school committee and not under the city board of health, as formerly. This will mean a reduction in the number of examining physicians from eighty to forty with an increase in salary to \$500 a year instead of \$300. The department of health will, however, maintain its staff of nurses to work among school children who need their services.

CONSTRUCTION OF LOCAL TUBERCULOSIS HOSPITALS AND DISPENSARIES.—In previous issues of the JOURNAL we have commented editorially on the law requiring the establishment and maintenance of tuberculosis hospitals and dispensaries in the various communities of this commonwealth. The enforcement of this law has been from time to time delayed, but it appears that by July 1, probably every town between ten thousand and fifty thousand inhabitants will, at least have plans under way for the construction of the required dispensary. Of the larger cities in which the law requires the construction of hospitals all but Brockton and Lowell have already complied with the law.

Massachusetts Medical Society.

ANNUAL MEETING OF THE SUPERVISORS.

At the annual meeting of the Supervising Censors, held in the Copley-Plaza Hotel, Boston, June 8, 1915, it was voted that the following report of the special committee appointed the previous year to consider the plan of examination of candidates for fellowship in the Society be printed in the BOSTON MEDICAL AND SURGICAL JOURNAL and assigned to a special meeting of the Supervisors, to be held on the day of the next meeting of the Council, Wednesday, October 6, 1915.

At the meeting of the Board of Supervisors, in June, 1914, the question was raised as to the advisability of a change in the method of examining candidates.

The present mode of examination was adapted to conditions which no longer obtain. At the time this mode was instituted the range of medical knowledge was so restricted that a well informed physician could have a comprehensive grasp of the entire subject. A written examination, therefore, could be a fair test of attainment and was equally fair for all applicants.

To a limited extent such examinations are still a fair test for the recent graduate; but the development of specialties, many of which never involve the responsibility of practice, has developed a large number of men of high attainment whose fields of knowl-

edge may have little if any region in common with one another or with those of men in active practice. Even the active practitioner must inevitably leave far behind him much of the knowledge which is rightly considered a necessary part of the recent graduate's equipment.

In other words, the present type of examination is fair only to the recent graduate who is in training for it; while it is no test of the attainment of the specialist or the surgeon or physician of long experience.

If there is to be a written test to show that the candidate is sufficiently equipped to meet our standard, there must be sufficient latitude in the form of optional questions to give each candidate an opportunity to indicate his ability in the field of medicine which is covered by his active work.

In this connection it is well to recall that among the men most honored as members of our profession are those whose whole interest and time are devoted to such topics as chemical and biological research, sanitary engineering, social service, the abstruse problems of psychology, the history of medicine and many other subjects far afield from the region commonly thought of as practical medicine.

The matter of admission to the Society cannot be treated adequately without a clear understanding of the objects of the Society, and its policy as to what members of the profession it seeks to include.

Your committee believes the Massachusetts Medical Society does not consider itself in the light of an academy—membership in which is a mark of extraordinary attainment or distinguished service. Neither is it meant to be exclusively a body of practitioners of medicine. Its aim is rather to include the entire reputable body of the profession—every graduate of a recognized school who is reasonably proficient and whose character is satisfactory.

Granting these two premises:

1. The extraordinary diversity of legitimate medical vocations as a result of the recent growth and expansion of what is properly called medicine.

2. What may be called the Society's policy of inclusiveness, the conditions for admission must be viewed in a new light.

It is plain that our present system of written examination is not adapted to meet the situation of today. It does not allow for legitimate diversity of knowledge or vocation. It is easiest for the recent graduate who is in training for examinations of such a kind, having just passed both medical school and state license examinations. It takes no account of experience and judgment, to say nothing of character established by years of practice.

Moreover the system is farcically unjust in its discrimination. A member of a state society in another state is exempt from written examination, no matter how inferior he may be.

On the other hand, a physician of this state; or a physician of another state who either has not joined his state society or has resigned from it is constrained to take the written examination no matter how eminent he may be as a physician or how honored as a man.

Your committee has canvassed opinion sufficiently to discover that it is far from unanimous as to the proper solution of this problem.

The more important suggestions are:

1. Retention of the written examination for all candidates—the paper to be so broad in scope, through alternative questions, that it will meet the problem of diversity.

A few would have the paper much stiffer, if anything, to raise the standard.

2. A modification of the method of marking by allowing a certain per cent. for each five years since graduation, to allow for the narrowing of the field of active work.

3. Abolition of written examination; and reliance

on the attainment of a degree from a school recognized by the Society, and the passing of the State Board as presumptive evidence of preliminary training; with reliance on the oral examination by the Censors to check up any doubts in individual cases, the chief function of the Censors being to determine whether or not the candidate gives evidence through his record and his general bearing that he is desirable as a member.

Your committee believes an examination paper fulfilling the necessary conditions would be impracticable; and is of the opinion that the best solution is presented by abolition of the written test and development of the oral examination, in which the personal equation of the candidate and his record would be important in determining his mark—a wide margin being left to the discretion of the Censors.

It may be said that with the abolition of the written examination the desired uniformity of the examination is lost. But the obvious reply is that even though the printed questions are the same for each district, there can be no uniform standard of marking when there are different sets of examiners for each district.

It has been asked whether the abolition of the written examination could be accomplished without an amendment of the By-laws.

A careful examination of the By-laws shows that a written examination is not specified. The only thing required is that there shall be an examination which satisfies the Censors of the suitability of the candidate.

That the Censors may see fit to give a written examination is implied by two provisions which specify that certain classes of candidates "shall be exempt from written examination."

Before making any radical change there is so much to be considered, and it is so evident that the Supervising Censors have, as yet, given but little thought to this problem, your committee suggests that it would be well to hold a special meeting for a general discussion of the matter.

Respectfully submitted,

G. A. CRAGIN, *Chairman*,
C. D. WHEELER,
N. P. BREED.

Obituary

JOHN HILDRETH MCCOLLOM, M.D.

John Hildreth McCollom, M.D., Harvard, '69; S. M., Dartmouth, '10, died suddenly on Monday morning, June 14, 1915, of angina pectoris. Having been in about his usual health up to the time of retiring, he awoke in the night suffering from the intense "breast pang" so characteristic of angina and died in less than an hour. There had been no premonitory symptoms of the trouble.

Dr. McCollom, the son of Rev. James T. and Elizabeth Phillips (Hildreth) McCollom, was born in Pittston, Me., on May 6, 1843. He graduated from Phillips Andover Academy in 1861 and entered Dartmouth College, where he remained one year. He then entered the army, enlisting in the 30th Massachusetts Infantry. He was made hospital steward and served in that capacity until the close of the war. He saw service in the attacks on the forts below New

Orleans, in the battle of Baton Rouge, at the siege of Vicksburg, in the Shenandoah Valley, at the battles of Winchester, Cedar Creek, etc. He was mustered out of the army in April, '65, and entered the Harvard Medical School, whence he graduated in '69 at the close of a year's service as house surgeon at the Boston City Hospital. He was assistant superintendent at the Marine Hospital in Chelsea for a year or more and finally settled in Boston and entered general practice in 1871.

Dr. McCollom at once became interested in contagious diseases and was appointed assistant to the city physician, having charge of vaccination and the smallpox patients. He once told the writer that he must have vaccinated at least 75,000 persons and that he had never seen a serious result from the operation. He was an early advocate of animal virus, not that it was any greater protection against smallpox, but because it removed the practically groundless fear of conveying other diseases. In 1881 he was made city physician of Boston and held this position until the contagious department of the City Hospital was established in 1895. He was placed in charge of that department and remained there 19 years, making it one of the leading contagious departments in the country.

It was here that Dr. McCollom did his best work—work that is epochal in its way and which places him in the front rank of medical benefactors. To him more than to any one else is doubtless due the present efficient and almost universal practice of giving large doses of antitoxin in diphtheria; doses that are limited in amount only by their effect upon the disease. In the early days of this agent the dose was limited to from three to five thousand units. Dr. McCollom pushed it to 50,000 units and repeated it frequently until he obtained the beneficial results he desired. Three hundred thousand units have been given at a single dose with benefit. Not only have many lives been saved by this method, but much suffering and disability in the way of paralysis, etc., have been prevented. No one unacquainted with pre-antitoxin days can begin to comprehend the radical change brought about by the free and timely use of this agent as inaugurated and advocated far and wide by the subject of this sketch. Many thousands of lives and an untold amount of suffering have been saved thereby. The mortality of this disease at the City Hospital is less than one-fourth of its former amount. Since the introduction of antitoxin there has not been a death among the house doctors, nurses and orderlies from this disease, although there have been nearly 500 cases that have received the treatment therefor. This surprising control of a dreadful affection is due entirely to the prompt and free use of the antitoxin.

Upon the retirement of Dr. Rowe from the position of superintendent and medical director

of the City Hospital in 1908, Dr. McCollom was promoted to that office. He rendered faithful and efficient service in that position until compelled by reason of failing eyesight from cataracts to resign. His resignation took effect on January 31, 1915.

Dr. McCollom's ability as a writer is shown by numerous excellent articles on various medical subjects to be found in the journals, systems of medicine, etc., during the past 40 years. As might be expected, his chief topics of interest were the contagious affections, as diphtheria, scarlet fever, measles, smallpox, etc. His charts showing the practical abolition of smallpox in Boston by vaccination and quarantine, are models of reliability. The exact truth was always his main object. A close student, a faithful observer, a conservative reasoner, his opinions were sound and his advice reliable.

As a teacher, the doctor has rendered excellent service to students in the Harvard Medical School during seventeen years. He was appointed instructor in contagious diseases in 1896, assistant professor in 1903 and professor in 1908. Upon his retirement from the School in 1913, he was made professor emeritus of contagious diseases. He was a member of the Senior Staff of the City Hospital as "Physician for Infectious Diseases." He was a member of numerous medical societies, as the American Medical Association, American Association of Pathologists and Bacteriologists, American Pediatric Society, Massachusetts Medical Society, Boston Society of Medical Science, etc. He was also a member of several clubs, as the St. Botolph, the University, the Harvard and Tavern Clubs, the New England Historical and Genealogical Society, the Harvard Medical Alumni Association and of Aberdour Lodge, A. F. and A. M. In 1875 he married Miss Susan Cartee, who survives him. There are no children.

Dr. McCollom led a busy, useful life, devoted entirely to his professional work. Even his vacations, especially those taken in Europe, were largely given up to investigating contagious hospitals, their methods of construction and administration. For many years he was the leading authority in this part of the country on contagious disease. His large experience at the City Hospital peculiarly fitted him for that position in the professional world. Brought up in an intellectual atmosphere, he was a man of wide reading and culture. Loyal to his friends and to his profession, kindly and self-sacrificing, always doing his utmost for the comfort and welfare of those in his care, always at his post of duty, his natural disposition and his military training combined to make him one of the most dependable of men. You knew where to find him. He had no side issues to distract his attention. The profession and the community trusted him implicitly. His character, his training and his daily life inspired confidence.

His personal and professional modesty was unvarying. He did good work and its results will be a lasting benefit to humanity.

This imperfect tribute to Dr. McCollom may well close with a liberal quotation from a letter sent him by the trustees upon his retirement from the City Hospital.

"Dear Dr. McCollom:—Your letter tendering your resignation as superintendent and medical director of the Boston City Hospital, owing to the advice of your physician, has been laid before the trustees at the meeting this day, and regretfully accepted.

"The trustees are exceedingly sorry that your health has compelled you to take this step. They are reluctant to part with an associate with whom they have enjoyed such long and pleasant relations, and one whose unflagging zeal and earnest and untiring efforts for its welfare have contributed very much to the up-building and the high standing of the Hospital. But above all else stands the record of the great work you have done for the South Department, which will be a monument to you more enduring than bronze or stone. Your unfaltering faith and courage in the use of antitoxin, which has so marvellously decreased the death rate from diphtheria, has saved to the world many thousands of useful lives and a grateful public will ever hold your name in high appreciation and gratitude for your noble services and research. After 42 years of faithful service for the city of Boston, you have the consciousness of having achieved and merited a position that places you in the front ranks of the benefactors of mankind. In your retirement you carry with you the well wishes and high commendation of the trustees and the public. The trustees extend to you their sincere sympathy and the hope that a well-earned rest may restore such measure of health as to enable you to pass many years in comfort and enjoyment."

GEORGE W. GAY, M.D.

Boston, June 16, 1915.

Correspondence

THE AMERICAN HOSPITAL OF PARIS.

SECTION FOR THE WOUNDED.

NEUILLY-SUR-SEINE, May 22, 1915.

Mr. Editor: On reaching Paris, April 1st, the Harvard Unit took over a service of 162 beds in the American Ambulance. Since that time, other beds have been added to the service until we now have something over 190 beds. For a week or so after we first came not all the beds were filled, but for the last three weeks we have had practically no empty beds. Thirty-three cases in 24 hours is the largest number of admissions we have had, and 16 major operative cases has been our heaviest operative day.

The virulent infections with gas-producing organisms, of which there were a number of cases early in April, have become less common as the season ad-

vanced and warm and drier weather followed the cold and rainy period of the early spring. Most of our cases reach us on the second or third day after injury. The wounds are usually infected when we get them. In April almost every wound showed gas-bacilli on culture. In May the proportion of such cases has fallen off materially. At present the ordinary pus-producing organisms are the ones most commonly found in cultures of fresh wounds. Almost every wound contains more or less of the clothing of the soldier, carried in by the missile, but the wounds produced by shell fragments are more frequently contaminated in this way than the bullet wounds. The bullet wounds are the most common injuries, followed closely by wounds from shell fragments. Shrapnel injuries are much less common.

Soldiers severely wounded in head, spine or abdomen are not easily transportable and, therefore, do not reach the base hospitals like this one. Most of our cases are penetrating or perforating wounds of the soft parts with or without bone injuries. The bone cases are among the worst with which we have to deal. A septic compound fracture of such long bones as the humerus or the femur is a very difficult case to handle. In almost every case the bone is shattered into many little pieces and these bone fragments are driven into the tissues in every direction and act like foreign bodies, to prevent healing until they are removed. We have been greatly helped in our work on these cases, by plaster and metal splints devised for each individual case by Dr. Osgood.

Up to May 20th, including the cases we took over when we first came, we have had 370 cases on our service. We have had three deaths, (1) brain abscess and meningitis, (2) perforations of the lung and hemorrhage and (3) diffuse perforative peritonitis; the last case died 10 minutes after entrance to the hospital.

It may interest you to see the list of operative cases we have had. Among the most interesting operations have been cerebral cases upon which Dr. Cushing operated. In two of these cases he was able to remove shell fragments from the brain, by use of the electro-magnet. Dr. Cushing had also two cases of peripheral nerve injury, one a plastic upon the facial nerve, and another upon the musculo-spiral.

Dr. Vincent has had one case for transfusion at this hospital and demonstrated his method of performing this operation also at Dr. Carrel's hospital in Compiègne. There have been other cases in this hospital on other services where Dr. Vincent's apparatus has been used. Dr. Osgood has had a number of orthopedic cases for operation, lengthening tendons and so on, and has contributed very materially to the success of the general service by devising and applying apparatus for retaining the position of difficult compound fractures. On the general service we have had a number of bone cases for operation, plating fractures of the femur, tibia and jaw and a plastic on a jaw with the insertion of a bone graft from a rib. We have been very fortunate so far in that we have had no cases that required amputation on our service, and no cases of secondary hemorrhage have occurred, although both conditions are ordinarily to be expected in a service such as this.

The moral and physical condition of the French soldiers has made a very favorable impression upon all of us. Some of the wounded reach us in a state of very great physical and mental depression. This is not unnatural under the circumstances in spite of the very excellent system of hospital trains which has been established by the French Government for the transport of wounded from the evacuation hospitals to the base hospitals. These trains are well equipped for ambulatory and stretcher cases, and are used exclusively for this service; they arrive in Paris at the freight station at La Chapelle, as a rule, some time in the night. The station has been equipped with portable houses erected on the platform, and a competent staff of orderlies, surgeons and nurses is

on hand to take the wounded from the train, feed them, do emergency dressings and attend to their distribution among the many military hospitals in and about Paris. The distribution of these cases is accomplished in a very orderly manner and the whole system of handling the wounded even under stress is working well. We were told that 2000 wounded were brought to Paris by these trains in one 24-hour period after the fighting at Ypres.

There are many Red Cross hospitals in operation in Paris beside the American Ambulance, although that is the largest one outside of the regular French military hospitals. The Russians and the Japanese have each a hospital in Paris and the English have a large hospital at Versailles. Most of the English wounded, however, are now evacuated to the Channel ports and carried immediately to England. We have about six English in the American Ambulance and almost all are cases that have been in the hospital for a long time. An American from the foreign legion was brought to the hospital the other day. The vast majority of our cases, however, are French with a few Turks and Senegalese.

The attitude of the French medical officers and of the government toward the American Ambulance is most cordial, and its work is held in high esteem by the soldiers as well as by the public.

Very truly yours,

ROBERT B. GREENOUGH, M.D.

LIST OF OPERATIONS PERFORMED DURING APRIL, 1915.

- April 4. Exploration and drainage of compound fracture, left humerus.
- " 7. Exploration for foreign body from right knee.
- " 7. Aspiration of chest.
- " 8. Plastic of cheek and lip.
- " 8. Exploration and drainage of compound fracture, right humerus.
- " 14. Disarticulation of head of left humerus (re-amputation).
- " 16. Freeing of left musculo-spiral nerve from scar.
- " 19. Plastic on left facial nerve.
- " " Removal of shrapnel from left thigh.
- " 20. Removal of bullet from right leg.
- " " Incision and drainage of left leg.
- " 21. Removal of foreign body from neck.
- " " Excision of ulcer of leg and plastic.
- " 22. Incision and drainage of left thigh.
- " 23. Cerebellar exploration for removal of shrapnel.
- " " Operation for radical cure, right mastoid.
- " " Drainage and curettage of right antrum of Highmore.
- " " Open reduction fracture of femur with bone plating.
- " " Radical cure of right femoral hernia.
- " " Manipulation of right elbow.
- " 25. Exploration of right eye and drainage of right antrum of Highmore. Incision and drainage of right hand.
- " " Incision and drainage of hand.
- " " Cleaning and draining of wound of arm.
- " " Exploration and cleaning shrapnel wounds of back.
- " 26. Exploration distal end of femur for foreign body.
- " " Incision and drainage of septic arm. Excision and suture of wounds of both thighs.
- " " Incision and drainage of septic arm.
- " 27. Laminectomy for division of spinal cord.
- " " Craniotomy for removal of shell fragments.
- " " Amputation of finger, left hand.
- " " Incision and drainage, septic finger. Cleaning and suturing wound, arm.
- " " Incision and drainage of septic arm.
- " 28. Cranial exploration for foreign body.

- April 28. Incision and drainage of septic hand.
 " " Incision and drainage of wounds of both thighs.
 " 29. Incision and drainage of leg.
 " " Incision and drainage of wound of right thigh. Removal of shell fragment.
 " " Cranial exploration for removal of foreign body, and drainage.
 " " Incision and drainage of foot.
 " 30. Exploration of sinus of leg and drainage.
 " " Incision and drainage of thigh.
 " " Right subtemporal decompression and drainage of old wound of skull.
 " " Craniotomy, exploratory and drainage.
 " " Incision and drainage of foot, and removal of foreign body.

[NOTE.—The above letter was received for simultaneous publication in this JOURNAL and in the *Harvard Alumni Bulletin*.—EDITOR.]

PRUDENTIAL HOSPITAL ASSOCIATION.

BOSTON, June 17, 1915.

Mr. Editor: I have just received a letter from a physician who asks my opinion of the Prudential Hospital Association. This physician states that a gentleman claiming to represent this association called upon him, stated that he had been sent by me, and that I had associated myself with the institution. My only knowledge of the Prudential Hospital Association is derived from an article that recently appeared in the daily press. This knowledge is not sufficient to warrant me in expressing an opinion as to the merits or demerits of the plan. The use of my name in connection with the project is entirely unauthorized.

Yours very truly,
 HORACE D. ARNOLD, M.D.

Miscellany.

 Pittsburg, Pa.

RECENT DEATHS.

DR. OTTO MARKUS, who was killed by a shell in the battle of the Argonne, had served as assistant in the medical clinic in the University of Würzburg. He was the author of numerous valuable contributions in neurology and psychiatry and prior to the war had been engaged in research on histology of the ganglion cells of the vegetative nervous system.

DR. JOHN MASON HASTINGS, a Fellow of The Massachusetts Medical Society having a residence in Dorchester, died at Provincetown, Mass., on June 10. He received the degree of M.D. from the Harvard Medical School in 1895, having previously graduated with the degree of A.B. from Bowdoin College in 1891. He was physician to the gynecological out-patient department of the Carney Hospital and a member of the American Medical Association and the Dorchester Medical Society.

DR. HENRY JAMES, who died at Waterbury, Vt., on June 10, was born in 1832. During the Civil War he commanded the hospital ship *Maine* and subsequently became surgeon-general of the Vermont National Guard. He was professor of surgery at the University of Vermont Medical College. He was a member of the American Medical Association, an honorary member of the California Medical Society, a member of the Vermont Medical Society and a former member of The Massachusetts Medical Society from 1857 to 1876.

DR. ALFRED MITCHELL, who died on June 13 at Brunswick, Maine, was born in 1837. He received the degree of M.D. in 1865 from the New York College of Physicians and Surgeons, having previously graduated from Bowdoin College. During the Civil War he served as assistant surgeon of the Ninth Maine Volunteers. At the close of the war he settled at Brunswick, where he continued active in the practise of his profession until his retirement in 1914. He served from 1869 to 1911 as dean of the Maine Medical School. In 1892 and 1893 he was president of the Maine Medical Association. He is survived by three daughters and one son.

DR. FREDERICK MORTIMER HEMENWAY, who died on June 13 in Allston, Mass., was born at Framingham, Mass., on November 29, 1848. He studied dentistry as an apprentice to Dr. C. B. Erickson at Hartford, Conn. Coming to Boston in 1882, he entered the Boston Dental College from which he received the degree of D.M.D. in 1888, since which time he had practised his profession in this city. From 1896 to 1912 he was professor of prosthetic dentistry in the Tufts Dental School. He was a member of the Massachusetts Dental Society. He is survived by his widow and by two sons.

DR. JOSEPH PREVETT, of Boston, who died on June 6 at Derry, N. H., was born in Italy in 1880. Coming to the United States he settled at Boston in 1903 and since that time had practised his profession in this city. He is survived by his widow and three children.
